

Chipsmall Limited consists of a professional team with an average of over 10 year of expertise in the distribution of electronic components. Based in Hongkong, we have already established firm and mutual-benefit business relationships with customers from,Europe,America and south Asia,supplying obsolete and hard-to-find components to meet their specific needs.

With the principle of “Quality Parts,Customers Priority,Honest Operation,and Considerate Service”,our business mainly focus on the distribution of electronic components. Line cards we deal with include Microchip,ALPS,ROHM,Xilinx,Pulse,ON,Everlight and Freescale. Main products comprise IC,Modules,Potentiometer,IC Socket,Relay,Connector.Our parts cover such applications as commercial,industrial, and automotives areas.

We are looking forward to setting up business relationship with you and hope to provide you with the best service and solution. Let us make a better world for our industry!

3.3V MULTI-QUEUE FLOW-CONTROL DEVICES (4 QUEUES) 36 BIT WIDE CONFIGURATION

589,824 bits
1,179,648 bits
2,359,296 bits

IDT72V51236
IDT72V51246
IDT72V51256

FEATURES:

- Choose from among the following memory density options:
IDT72V51236 — Total Available Memory = 589,824 bits
IDT72V51246 — Total Available Memory = 1,179,648 bits
IDT72V51256 — Total Available Memory = 2,359,296 bits
- Configurable from 1 to 4 Queues
- Queues may be configured at master reset from the pool of Total Available Memory in blocks of 256 x 36
- Independent Read and Write access per queue
- User programmable via serial port
- Default multi-queue device configurations
-IDT72V51236: 4,096 x 36 x 4Q
-IDT72V51246: 8,192 x 36 x 4Q
-IDT72V51256: 16,384 x 36 x 4Q
- 100% Bus Utilization, Read and Write on every clock cycle
- 166 MHz High speed operation (6ns cycle time)
- 3.7ns access time
- Individual, Active queue flags (\overline{OV} , \overline{FF} , \overline{PAE} , \overline{PAF} , \overline{PR})

- 4 bit parallel flag status on both read and write ports
- Provides continuous \overline{PAE} and \overline{PAF} status of up to 4 Queues
- Global Bus Matching - (All Queues have same Input Bus Width and Output Bus Width)
- User Selectable Bus Matching Options:
- x36in to x36out
- x18in to x36out
- x9in to x36out
- x36in to x18out
- x36in to x9out
- FWFT mode of operation on read port
- Packet mode operation
- Partial Reset, clears data in single Queue
- Expansion of up to 8 multi-queue devices in parallel is available
- JTAG Functionality (Boundary Scan)
- Available in a 256-pin PBGA, 1mm pitch, 17mm x 17mm
- HIGH Performance submicron CMOS technology
- Industrial temperature range (-40°C to +85°C) is available

FUNCTIONAL BLOCK DIAGRAM

DESCRIPTION:

The IDT72V51236/72V51246/72V51256 multi-queue flow-control devices are single chip within which anywhere between 1 and 4 discrete FIFO queues can be setup. All queues within the device have a common data input bus, (write port) and a common data output bus, (read port). Data written into the write port is directed to a respective queue via an internal de-multiplex operation, addressed by the user. Data read from the read port is accessed from a respective queue via an internal multiplex operation, addressed by the user. Data writes and reads can be performed at high speeds up to 166MHz, with access times of 3.7ns. Data write and read operations are totally independent of each other, a queue may be selected on the write port and a different queue on the read port or both ports may select the same queue simultaneously.

The device provides Full flag and Output Valid flag status for the queue selected for write and read operations respectively. Also a Programmable Almost Full and Programmable Almost Empty flag for each queue is provided. Two 4 bit programmable flag busses are available, providing status of all queues, including queues not selected for write or read operations, these flag busses provide an individual flag per queue.

Bus Matching is available on this device, either port can be 9 bits, 18 bits or 36 bits wide provided that at least one port is 36 bits wide. When Bus Matching is used the device ensures the logical transfer of data throughput in a Little Endian manner.

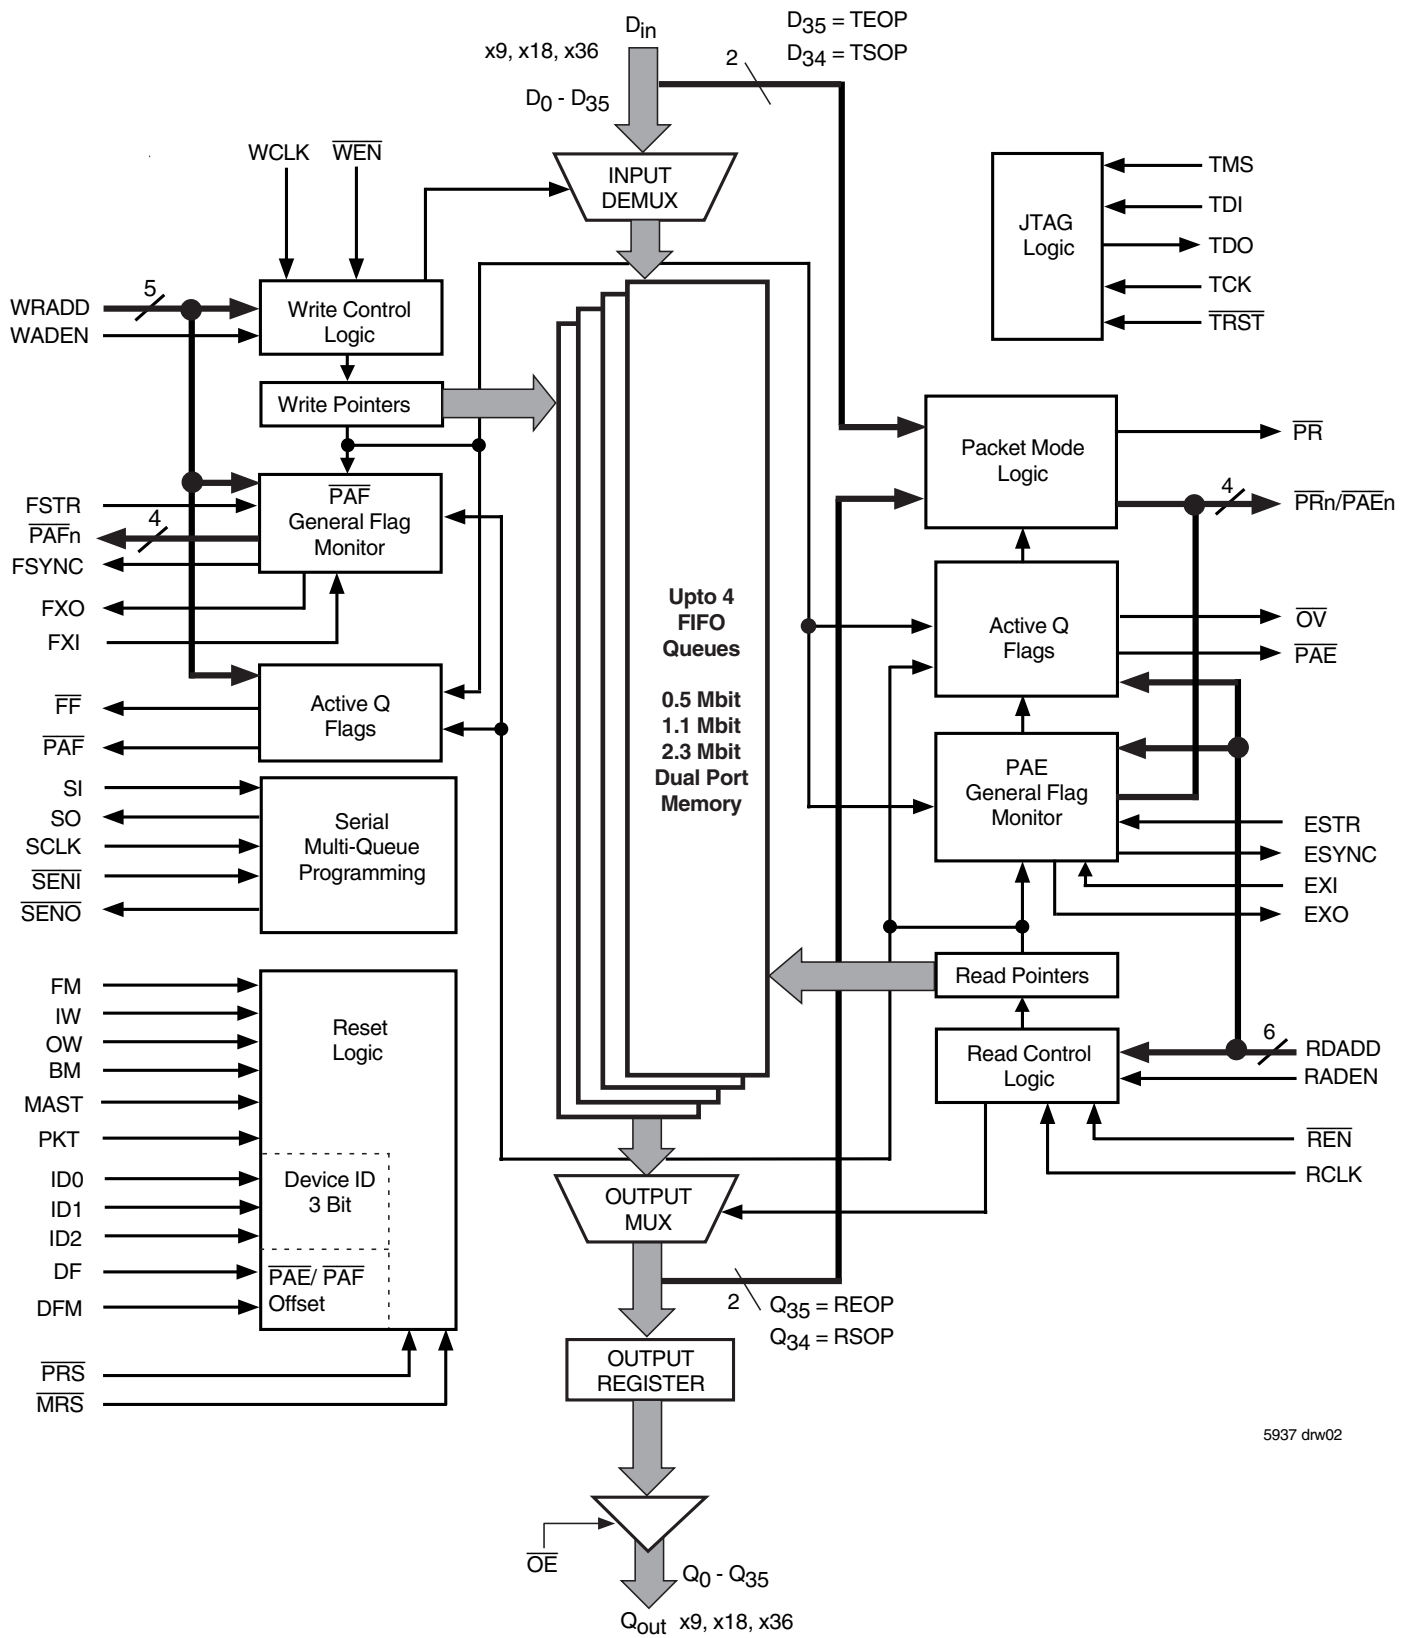

A packet mode of operation is also provided when the device is configured for 36 bit input and 36 bit output port sizes. The Packet mode provides the user with a flag output indicating when at least one (or more) packets of data within a queue is available for reading. The Packet Ready provides the user with a means by which to mark the start and end of packets of data being passed through the queues. The multi-queue device then provides the user with an internally generated packet ready status per queue.

The user has full flexibility configuring queues within the device, being able to program the total number of queues between 1 and 4, the individual queue depths being independent of each other. The programmable flag positions are also user programmable. All programming is done via a dedicated serial port. If the user does not wish to program the multi-queue device, a default option is available that configures the device in a predetermined manner.

Both Master Reset and Partial Reset pins are provided on this device. A Master Reset latches in all configuration setup pins and must be performed before programming of the device can take place. A Partial Reset will reset the read and write pointers of an individual queue, provided that the queue is selected on both the write port and read port at the time of partial reset.

A JTAG test port is provided, here the multi-queue flow-control device has a fully functional Boundary Scan feature, compliant with IEEE 1149.1 Standard Test Access Port and Boundary Scan Architecture.

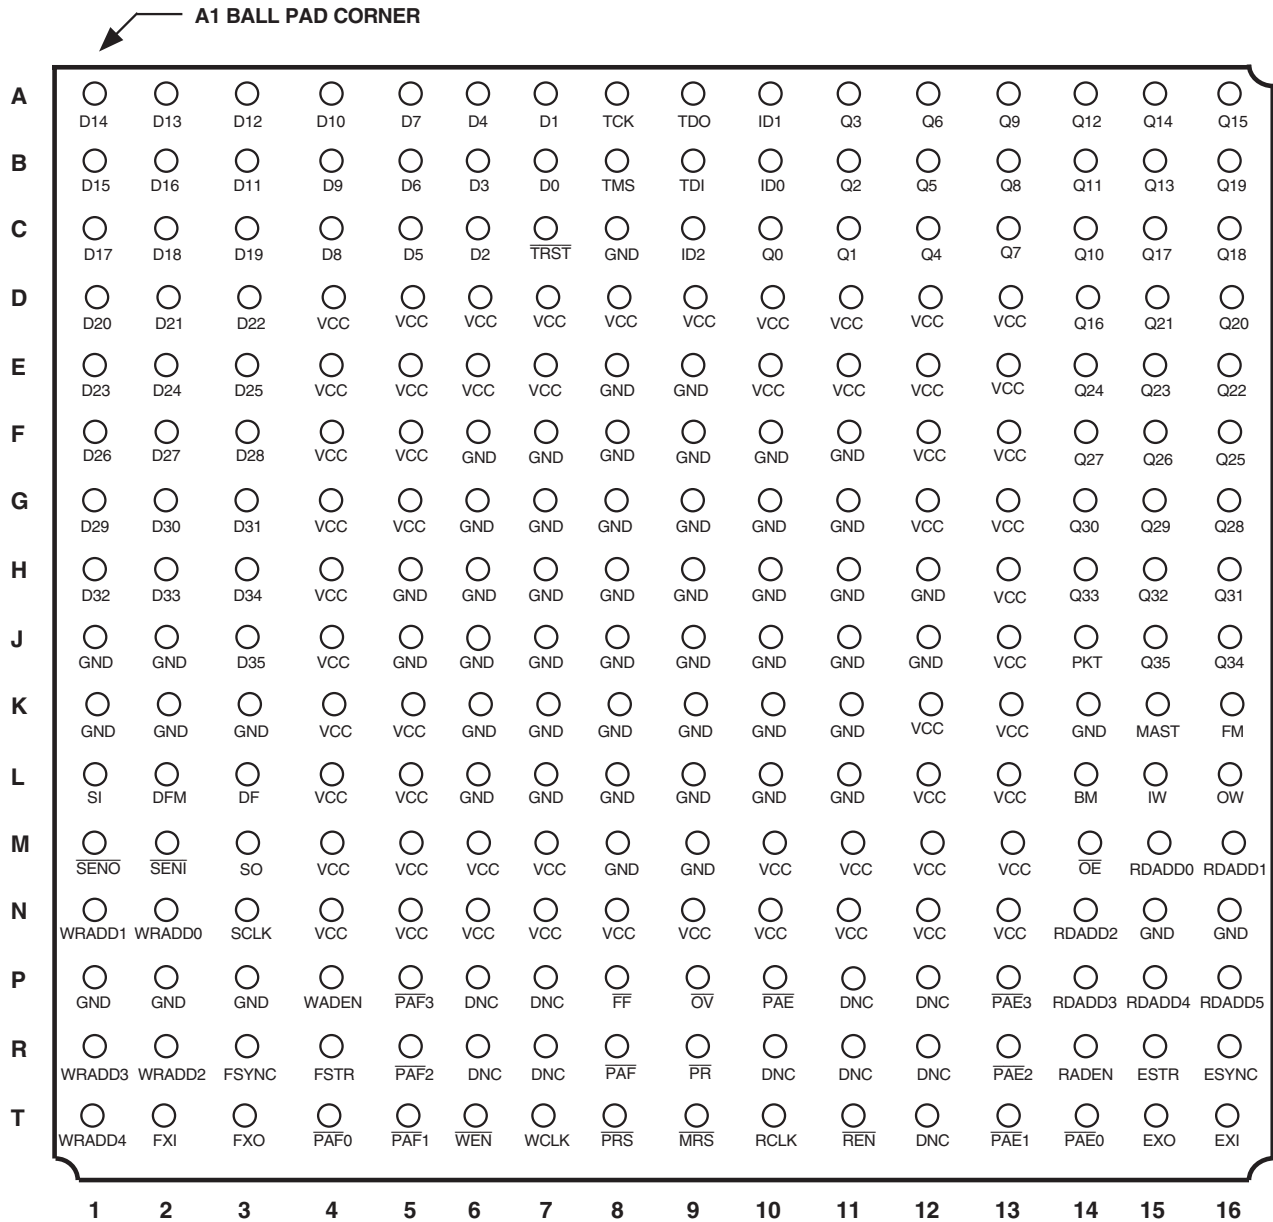

See Figure 1, *Multi-Queue Flow-Control Device Block Diagram* for an outline of the functional blocks within the device.

DETAILED DESCRIPTION

MULTI-QUEUE STRUCTURE

The IDT multi-queue flow-control device has a single data input port and single data output port with up to 4 FIFO queues in parallel buffering between the two ports. The user can setup between 1 and 4 Queues within the device. These queues can be configured to utilize the total available memory, providing the user with full flexibility and ability to configure the queues to be various depths, independent of one another.

MEMORY ORGANIZATION/ALLOCATION

The memory is organized into what is known as “blocks”, each block being 256x36 bits. When the user is configuring the number of queues and individual queue sizes the user must allocate the memory to respective queues, in units of blocks, that is, a single queue can be made up from 0 to m blocks, where m is the total number of blocks available within a device. Also the total size of any given queue must be in increments of 256 x36. For the IDT72V51236/72V51246 and IDT72V51256 the Total Available Memory is 64, 128 and 256 blocks respectively (a block being 256 x36). Queues can be built from these blocks to make any size queue desired and any number of queues desired.

BUS WIDTHS

The input port is common to all queues within the device, as is the output port. The device provides the user with Bus Matching options such that the input port and output port can be either x9, x18 or x36 bits wide provided that at least one of the ports is x36 bits wide, the read and write port widths being set independently of one another. Because the ports are common to all queues the width of the queues is not individually set, so that the input width of all queues are equal and the output width of all queues are equal.

WRITING TO & READING FROM THE MULTI-QUEUE

Data being written into the device via the input port is directed to a discrete queue via the write queue select address inputs. Conversely, data being read from the device read port is read from a queue selected via the read queue select address inputs. Data can be simultaneously written into and read from the same queue or different queues. Once a queue is selected for data writes or reads, the writing and reading operation is performed in the same manner as conventional IDT synchronous FIFO, utilizing clocks and enables, there is a single clock and enable per port. When a specific queue is addressed on the write port, data placed on the data inputs is written to that queue sequentially based on the rising edge of a write clock provided setup and hold times are met. Conversely, data is read on to the output port after an access time from a rising edge on a read clock.

The operation of the write port is comparable to the function of a conventional FIFO operating in standard IDT mode. Write operations can be performed on the write port provided that the queue currently selected is not full, a full flag output provides status of the selected queue. The operation of the read port is comparable to the function of a conventional FIFO operating in FWFT mode. When a queue is selected on the output port, the next word in that queue will automatically fall through to the output register. All subsequent words from that queue require an enabled read cycle. Data cannot be read from a selected queue if that queue is empty, the read port provides an Output Valid flag indicating when data read out is valid. If the user switches to a queue that is empty, the last word from the previous queue will remain on the output register.

As mentioned, the write port has a full flag, providing full status of the selected queue. Along with the full flag a dedicated almost full flag is provided, this almost full flag is similar to the almost full flag of a conventional IDT FIFO. The device

provides a user programmable almost full flag for all 4 queues and when a respective queue is selected on the write port, the almost full flag provides status for that queue. Conversely, the read port has an output valid flag, providing status of the data being read from the queue selected on the read port. As well as the output valid flag the device provides a dedicated almost empty flag. This almost empty flag is similar to the almost empty flag of a conventional IDT FIFO. The device provides a user programmable almost empty flag for all 4 queues and when a respective queue is selected on the read port, the almost empty flag provides status for that queue.

PROGRAMMABLE FLAG BUSES

In addition to these dedicated flags, full & almost full on the write port and output valid & almost empty on the read port, there are two flag status buses. An almost full flag status bus is provided, this bus is 4 bits wide. Also, an almost empty flag status bus is provided, again this bus is 4 bits wide. The purpose of these flag buses is to provide the user with a means by which to monitor the data levels within queues that may not be selected on the write or read port. As mentioned, the device provides almost full and almost empty registers (programmable by the user) for each of the 4 queues in the device.

The 4 bit $\overline{\text{PAEn}}$ and 4 bit $\overline{\text{PAFn}}$ buses provide a discrete status of the Almost Empty and Almost Full conditions of all 4 queue's. If the device is programmed for less than 4 queue's, then there will be a corresponding number of active outputs on the $\overline{\text{PAEn}}$ and $\overline{\text{PAFn}}$ buses.

The flag buses can provide a continuous status of all queues. If devices are connected in expansion mode the individual flag buses can be left in a discrete form, providing constant status of all queues, or the buses of individual devices can be connected together to produce a single bus of 4 bits. The device can then operate in a "Polled" or "Direct" mode.

When operating in polled mode the flag bus provides status of each device sequentially, that is, on each rising edge of a clock the flag bus is updated to show the status of each device in order. The rising edge of the write clock will update the Almost Full bus and a rising edge on the read clock will update the Almost Empty bus.

When operating in direct mode the device driving the flag bus is selected by the user. The user addresses the device that will take control of a respective flag bus, these $\overline{\text{PAFn}}$ and $\overline{\text{PAEn}}$ flag buses operating independently of one another. Addressing of the Almost Full flag bus is done via the write port and addressing of the Almost Empty flag bus is done via the read port.

PACKET MODE

The multi-queue flow-control device also offers a “Packet Mode” operation. Packet Mode is user selectable and requires the device to be configured with both write and read ports as 36 bits wide. In packet mode, users can define the length of packets or frame by using the two most significant bits of the 36-bit word. Bit 34 is used to mark the Start of Packet (SOP) and bit 35 is used to mark the End of Packet (EOP) as shown in Table 5). When writing data into a given queue, the first word being written is marked, by the user setting bit 34 as the “Start of Packet” (SOP) and the last word written is marked as the “End of Packet” (EOP) with all words written between the Start of Packet (SOP) marker (bit 34) and the End of packet (EOP) packet marker (bit 35) constituting the entire packet. A packet can be any length the user desires, up to the total available memory in the multi-queue flow-control device. The device monitors the SOP (bit 34) and looks for the word that contains the EOP (bit 35). The read port is supplied with an additional status flag, “Packet Ready”. The Packet Ready ($\overline{\text{PR}}$) flag in conjunction with Output Valid ($\overline{\text{OV}}$) indicates when at least one packet is available to read. When in packet mode the almost empty flag status, provides packet ready flag status for individual queues.

EXPANSION

Expansion of multi-queue devices is also possible, up to 8 devices can be connected in a parallel fashion providing the possibility of both depth expansion or queue expansion. Depth Expansion means expanding the depths of individual queues. Queue expansion means increasing the total number of queues available. Depth expansion is possible by virtue of the fact that more memory blocks within a multi-queue device can be allocated to increase the depth of a queue. For example, depth expansion of 8 devices provides the possibility of 8 queues of 64K x36 deep, each queue being setup within a single

device utilizing all memory blocks available to produce a single queue. This is the deepest queue that can setup within a device.

For queue expansion of the 4 queue device, a maximum number of 32 (8 x 4) queues may be setup, each queue being 2K x36 deep, if less queues are setup, then more memory blocks will be available to increase queue depths if desired. When connecting multi-queue devices in expansion mode all respective input pins (data & control) and output pins (data & flags), should be "connected" together between individual devices.

PIN DESCRIPTIONS

Symbol	Name	I/O TYPE	Description
BM	Bus Matching	LVTTL INPUT	This pin is setup before Master Reset and must not toggle during any device operation. This pin is used along with IW and OW to setup the multi-queue flow-control device bus width. Please refer to Table 3 for details.
D[35:0] Din	Data Input Bus	LVTTL INPUT	These are the 36 data input pins. Data is written into the device via these input pins on the rising edge of WCLK provided that \overline{WEN} is LOW. Note, that in Packet mode D32-D35 may be used as packet markers, please see packet ready functional discussion for more detail. Due to bus matching not all inputs may be used, any unused inputs should be tied LOW.
DF ⁽¹⁾	Default Flag	LVTTL INPUT	If the user requires default programming of the multi-queue device, this pin must be setup before Master Reset and must not toggle during any device operation. The state of this input at master reset determines the value of the $\overline{PAE}/\overline{PAF}$ flag offsets. If DF is LOW the value is 8, if DF is HIGH the value is 128.
DFM ⁽¹⁾	Default Mode	LVTTL INPUT	The multi-queue device requires programming after master reset. The user can do this serially via the serial port, or the user can use the default method. If DFM is LOW at master reset then serial mode will be selected, if HIGH then default mode is selected.
ESTR	\overline{PAEn} Flag Bus Strobe	LVTTL INPUT	If direct operation of the \overline{PAEn} bus has been selected, the ESTR input is used in conjunction with RCLK and the RDADD bus to select a device for its queues to be placed on to the \overline{PAEn} bus outputs. A device addressed via the RDADD bus is selected on the rising edge of RCLK provided that ESTR is HIGH. If Polled operations has been selected, ESTR should be tied inactive, LOW. Note, that a \overline{PAEn} flag bus selection cannot be made, (ESTR must NOT go active) until programming of the part has been completed and $\overline{SEN0}$ has gone LOW.
ESYNC	\overline{PAEn} Bus Sync	LVTTL OUTPUT	ESYNC is an output from the multi-queue device that provides a synchronizing pulse for the \overline{PAEn} bus during Polled operation of the \overline{PAEn} bus. During Polled operation each devices queue status flags are loaded on to the \overline{PAEn} bus outputs sequentially based on RCLK. The first RCLK rising edge loads device 1 on to \overline{PAEn} , the second RCLK rising edge loads device 2 and so on. During the RCLK cycle that a selected device is placed on to the \overline{PAEn} bus, the ESYNC output will be HIGH.
EXI	$\overline{PAEn}/\overline{PRn}$ Bus Expansion In	LVTTL INPUT	The EXI input is used when multi-queue devices are connected in expansion mode and Polled $\overline{PAEn}/\overline{PRn}$ bus operation has been selected. EXI of device 'N' connects directly to EXO of device 'N-1'. The EXI receives a token from the previous device in a chain. In single device mode the EXI input must be tied LOW if the $\overline{PAEn}/\overline{PRn}$ bus is operated in direct mode. If the $\overline{PAEn}/\overline{PRn}$ bus is operated in polled mode the EXI input must be connected to the EXO output of the same device. In expansion mode the EXI of the first device should be tied LOW, when direct mode is selected.
EXO	$\overline{PAEn}/\overline{PRn}$ Bus Expansion Out	LVTTL OUTPUT	EXO is an output that is used when multi-queue devices are connected in expansion mode and Polled $\overline{PAEn}/\overline{PRn}$ bus operation has been selected. EXO of device 'N' connects directly to EXI of device 'N+1'. This pin pulses HIGH when device N places its \overline{PAE} status on to the $\overline{PAEn}/\overline{PRn}$ bus with respect to RCLK. This pulse (token) is then passed on to the next device in the chain 'N+1' and on the next RCLK rising edge the first quadrant of device N+1 will be loaded on to the $\overline{PAEn}/\overline{PRn}$ bus. This continues through the chain and EXO of the last device is then looped back to EXI of the first device. The ESYNC output of each device in the chain provides synchronization to the user of this looping event.
\overline{FF}	Full Flag	LVTTL OUTPUT	This pin provides the full flag output for the active queue, that is, the queue selected on the input port for write operations, (selected via WCLK, WRADD bus and WADEN). On the WCLK cycle after a queue selection, this flag will show the status of the newly selected queue. Data can be written to this queue on the next cycle provided \overline{FF} is HIGH. This flag has High-Impedance capability, this is important during expansion of devices, when the \overline{FF} flag output of up to 8 devices may be connected together on a common line. The device with a queue selected takes control of the \overline{FF} bus, all other devices place their \overline{FF} output into High-Impedance. When a queue selection is made on the write port this output will switch from High-Impedance control on the next WCLK cycle. This flag is synchronized to WCLK.
FM ⁽¹⁾	Flag Mode	LVTTL INPUT	This pin is setup before a master reset and must not toggle during any device operation. The state of the FM pin during Master Reset will determine whether the \overline{PAFn} and \overline{PAEn} flag busses operate in either Polled or Direct mode. If this pin is HIGH the mode is Polled, if LOW then it will be Direct.
FSTR	\overline{PAFn} Flag Bus Strobe	LVTTL INPUT	If direct operation of the \overline{PAFn} bus has been selected, the FSTR input is used in conjunction with WCLK and the WRADD bus to select a device for its queues to be placed on to the \overline{PAFn} bus outputs. A device addressed via the WRADD bus is selected on the rising edge of WCLK provided that FSTR is HIGH. If

PIN DESCRIPTIONS (CONTINUED)

Symbol	Name	I/O TYPE	Description
FSTR (Continued)	$\overline{\text{PAF}}_n$ Flag Bus Strobe	LVTTL INPUT	Polled operations has been selected, FSTR should be tied inactive, LOW. Note, that a $\overline{\text{PAF}}_n$ flag bus selection cannot be made, (FSTR must NOT go active) until programming of the part has been completed and $\overline{\text{SEN}}_0$ has gone LOW.
FSYNC	$\overline{\text{PAF}}_n$ Bus Sync	LVTTL OUTPUT	FSYNC is an output from the multi-queue device that provides a synchronizing pulse for the $\overline{\text{PAF}}_n$ bus during Polled operation of the $\overline{\text{PAF}}_n$ bus. During Polled operation each quadrant of queue status flags is loaded on to the $\overline{\text{PAF}}_n$ bus outputs sequentially based on WCLK. The first WCLK rising edge loads device 1 on to the $\overline{\text{PAF}}_n$ bus outputs, the second WCLK rising edge loads device 2 and so on. During the WCLK cycle that a selected device is placed on to the $\overline{\text{PAF}}_n$ bus, the FSYNC output will be HIGH.
FXI	$\overline{\text{PAF}}_n$ Bus Expansion In	LVTTL INPUT	The FXI input is used when multi-queue devices are connected in expansion mode and Polled $\overline{\text{PAF}}_n$ bus operation has been selected. FXI of device 'N' connects directly to FXO of device 'N-1'. The FXI receives a token from the previous device in a chain. In single device mode the FXI input must be tied LOW if the $\overline{\text{PAF}}_n$ bus is operated in direct mode. If the $\overline{\text{PAF}}_n$ bus is operated in polled mode the FXI input must be connected to the FXO output of the same device. In expansion mode the FXI of the first device should be tied LOW, when direct mode is selected.
FXO	$\overline{\text{PAF}}_n$ Bus Expansion Out	LVTTL OUTPUT	FXO is an output that is used when multi-queue devices are connected in expansion mode and Polled $\overline{\text{PAF}}_n$ bus operation has been selected. FXO of device 'N' connects directly to FXI of device 'N+1'. This pin pulses HIGH when device N places its $\overline{\text{PAF}}$ status on to the $\overline{\text{PAF}}_n$ bus with respect to WCLK. This pulse (token) is then passed on to the next device in the chain 'N+1' and on the next WCLK rising edge the first quadrant of device N+1 will be loaded on to the $\overline{\text{PAF}}_n$ bus. This continues through the chain and FXO of the last device is then looped back to FXI of the first device. The FSYNC output of each device in the chain provides synchronization to the user of this looping event.
ID[2:0] ⁽¹⁾	Device ID Pins	LVTTL INPUT	For the 4Q multi-queue device the WRADD address bus is 5 bits and RDADD address bus is 6 bits wide. When a queue selection takes place the 3MSb's of this address bus are used to address the specific device (the LSb's are used to address the queue within that device). During write/read operations the 3MSb's of the address are compared to the device ID pins. The first device in a chain of Multi-Queue's (connected in expansion mode), may be setup as '000', the second as '001' and so on through to device 8 which is '111', however the ID does not have to match the device order. In single device mode these pins should be setup as '000' and the 3MSb's of the WRADD and RDADD address busses should be tied LOW. The ID[2:0] inputs setup a respective devices ID during master reset. These ID pins must not toggle during any device operation. Note, the device selected as the 'Master' does not have to have the ID of '000'.
IW ⁽¹⁾	Input Width	LVTTL INPUT	This pin is used in conjunction with OW and BM to setup the input and output bus widths to be a combination of x9, x18 or x36, (providing that one port is x36).
MAST ⁽¹⁾	Master Device	LVTTL INPUT	The state of this input at Master Reset determines whether a given device (within a chain of devices), is the Master device or a Slave. If this pin is HIGH, the device is the master, if it is LOW then it is a Slave. The master device is the first to take control of all outputs after a master reset, all slave devices go to High-Impedance, preventing bus contention. If a multi-queue device is being used in single device mode, this pin must be set HIGH.
$\overline{\text{MRS}}$	Master Reset	LVTTL INPUT	A master reset is performed by taking $\overline{\text{MRS}}$ from HIGH to LOW, to HIGH. Device programming is required after master reset.
$\overline{\text{OE}}$	Output Enable	LVTTL INPUT	The Output enable signal is an Asynchronous signal used to provide three-state control of the multi-queue data output bus, Qout. If a device has been configured as a "Master" device, the Qout data outputs will be in a Low Impedance condition if the $\overline{\text{OE}}$ input is LOW. If $\overline{\text{OE}}$ is HIGH then the Qout data outputs will be in High Impedance. If a device is configured a "Slave" device, then the Qout data outputs will always be in High Impedance until that device has been selected on the Read Port, at which point $\overline{\text{OE}}$ provides three-state of that respective device.
$\overline{\text{OV}}$	Output Valid Flag	LVTTL OUTPUT	This output flag provides output valid status for the data word present on the multi-queue flow-control device data output port, Qout. This flag is therefore, 2-stage delayed to match the data output path delay. That is, there is a 2 RCLK cycle delay from the time a given queue is selected for reads, to the time the $\overline{\text{OV}}$ flag represents the data in that respective queue. When a selected queue on the read port is read to empty, the $\overline{\text{OV}}$ flag will go HIGH, indicating that data on the output bus is not valid. The $\overline{\text{OV}}$ flag also has High-Impedance capability, required when multiple devices are used and the $\overline{\text{OV}}$ flags are tied together.

PIN DESCRIPTIONS (CONTINUED)

Symbol	Name	I/O TYPE	Description
OW ⁽¹⁾	OutputWidth	LVTTL INPUT	This pin is setup during Master Reset and must not toggle during any device operation. This pin is used in conjunction with IW and BM to setup the data input and output bus widths to be a combination of x9, x18 or x36, (providing that one port is x36).
$\overline{\text{PAE}}$	Programmable Almost-Empty Flag	LVTTL OUTPUT	This pin provides the Almost-Empty flag status for the queue that has been selected on the output port for read operations, (selected via RCLK, RDADD and RADEN). This pin is LOW when the selected queue is almost-empty. This flag output may be duplicated on one of the $\overline{\text{PAEn}}$ bus lines. This flag is synchronized to RCLK.
$\overline{\text{PAEn}}/\overline{\text{PRn}}$	Programmable Almost-Empty Flag Bus/ Packet Ready Flag Bus	LVTTL OUTPUT	On the 4Q device the $\overline{\text{PAEn}}/\overline{\text{PRn}}$ bus is 4 bits wide. During a Master Reset this bus is setup for either Almost Empty mode or Packet mode. This output bus provides $\overline{\text{PAE}}/\overline{\text{PR}}$ status of all 4 queues, within a selected device. During Queue read/write operations these outputs provide programmable empty flag status or packet ready status, in either director polled mode. The mode of flag operation is determined during master reset via the state of the FM input. This flag bus is capable of High-Impedance state, this is important during expansion of multi-queue devices. During direct operation the $\overline{\text{PAEn}}/\overline{\text{PRn}}$ bus is updated to show the $\overline{\text{PAE}}/\overline{\text{PR}}$ status of queues within a selected device. Selection is made using RCLK, ESTR and RDADD. During Polled operation the $\overline{\text{PAEn}}/\overline{\text{PRn}}$ bus is loaded with the $\overline{\text{PAE}}/\overline{\text{PR}}$ status of multi-queue flow-control devices sequentially based on the rising edge of RCLK. $\overline{\text{PAE}}$ or $\overline{\text{PR}}$ operation is determined by the state of PKT during master reset.
$\overline{\text{PAF}}$	Programmable Almost-Full Flag	LVTTL OUTPUT	This pin provides the Almost-Full flag status for the queue that has been selected on the input port for write operations, (selected via WCLK, WRADD and WADEN). This pin is LOW when the selected queue is almost-full. This flag output may be duplicated on one of the $\overline{\text{PAFn}}$ bus lines. This flag is synchronized to WCLK.
$\overline{\text{PAFn}}$	Programmable Almost-Full Flag Bus	LVTTL OUTPUT	On the 4Q device the $\overline{\text{PAFn}}$ bus is 4 bits wide. This output bus provides $\overline{\text{PAF}}$ status of all 4 queues, within a selected device. During Queue read/write operations these outputs provide programmable full flag status, in either direct or polled mode. The mode of flag operation is determined during master reset via the state of the FM input. This flag bus is capable of High-Impedance state, this is important during expansion of multi-queue devices. During direct operation the $\overline{\text{PAFn}}$ bus is updated to show the $\overline{\text{PAF}}$ status of a queues within a selected device. Selection is made using WCLK, FSTR, WRADD and WADEN. During Polled operation the $\overline{\text{PAFn}}$ bus is loaded with the $\overline{\text{PAF}}$ status of multi-queue flow-control devices sequentially based on the rising edge of WCLK.
PKT ⁽¹⁾	PacketMode	LVTTL INPUT	The state of this pin during a Master Reset will determine whether the part is operating in Packet mode providing both a Packet Ready ($\overline{\text{PR}}$) output and a Programmable Almost Empty ($\overline{\text{PAE}}$) discrete output, or standard mode, providing a ($\overline{\text{PAE}}$) output only. If this pin is HIGH during Master Reset the part will operate in packet mode, if it is LOW then almost empty mode. If packet mode has been selected the read port flag bus becomes packet ready flag bus, $\overline{\text{PRn}}$ and the discrete packet ready flag, $\overline{\text{PR}}$ is functional. If almost empty operation has been selected then the flag bus provides almost empty status, $\overline{\text{PAEn}}$ and the discrete almost empty flag, $\overline{\text{PAE}}$ is functional, the $\overline{\text{PR}}$ flag is inactive and should not be connected. Packet Ready utilizes user marked locations to identify start and end of packets being written into the device. Packet Mode can only be selected if both the input port width and output port width are 36 bits.
$\overline{\text{PR}}$	Packet Ready Flag	LVTTL	If packet mode has been selected this flag output provides Packet Ready status of the queue selected for read operations. During a master reset the state of the PKT input determines whether Packet mode of operation will be used. If Packet mode is selected, then the condition of the $\overline{\text{PR}}$ flag and $\overline{\text{OV}}$ signal are asserted indicates a packet is ready for reading. The user must mark the start of a packet and the end of a packet when writing data into a queue. Using these Start Of Packet (SOP) and End Of Packet (EOP) markers, the multi-queue device sets $\overline{\text{PR}}$ LOW if one or more "complete" packets are available in the queue. A complete packet(s) must be written before the user is allowed to switch queues.
$\overline{\text{PRS}}$	Partial Reset	LVTTL INPUT	A Partial Reset can be performed on a single queue selected within the multi-queue device. Before a Partial Reset can be performed on a queue, that queue must be selected on both the write port and read port 2 clock cycles before the reset is performed. A Partial Reset is then performed by taking $\overline{\text{PRS}}$ LOW for one WCLK cycle and one RCLK cycle. The Partial Reset will only reset the read and write pointers to the first memory location, none of the devices configuration will be changed.

PIN DESCRIPTIONS (CONTINUED)

Symbol	Name	I/O TYPE	Description
Q[35:0] Qout	Data Output Bus	LVTTL OUTPUT	These are the 36 data output pins. Data is read out of the device via these output pins on the rising edge of RCLK provided that \overline{REN} is LOW, \overline{OE} is LOW and the queue is selected. Note, that in Packet mode Q32-Q35 may be used as packet markers, please see packet ready functional discussion for more detail. Due to bus matching not all outputs may be used, any unused outputs should not be connected.
RADEN	Read Address Enable	LVTTL INPUT	The RADEN input is used in conjunction with RCLK and the RDADD address bus to select a queue to be read from. A queue addressed via the RDADD bus is selected on the rising edge of RCLK provided that RADEN is HIGH. RADEN should be asserted (HIGH) only during a queue change cycle(s). RADEN should not be permanently tied HIGH. RADEN cannot be HIGH for the same RCLK cycle as ESTR. Note, that a read queue selection cannot be made, (RADEN must NOT go active) until programming of the part has been completed and $\overline{SEN0}$ has gone LOW.
RCLK	Read Clock	LVTTL INPUT	When enabled by \overline{REN} , the rising edge of RCLK reads data from the selected queue via the output bus Qout. The queue to be read is selected via the RDADD address bus and a rising edge of RCLK while RADEN is HIGH. A rising edge of RCLK in conjunction with ESTR and RDADD will also select the device to be placed on the $\overline{PAEn/PRn}$ bus during direct flag operation. During polled flag operation the $\overline{PAEn/PRn}$ bus is cycled with respect to RCLK and the ESYNC signal is synchronized to RCLK. The PAE, PR and OV outputs are all synchronized to RCLK. During device expansion the EXO and EXI signals are based on RCLK. RCLK must be continuous and free-running.
RDADD [5:0]	Read Address Bus	LVTTL INPUT	For the 4Q device the RDADD bus is 6 bits. The RDADD bus is a dual purpose address bus. The first function of RDADD is to select a queue to be read from. The least significant 2 bits of the bus, RDADD[1:0] are used to address 1 of 4 possible queues within a multi-queue device. Address pin, RDADD[2] provides the user with a Null-Q address. If the user does not wish to address one of the 4 queues, a Null-Q can be addressed using this pin. The Null-Q operation is discussed in more detail later. The most significant 3 bits, RDADD[5:3] are used to select 1 of 8 possible multi-queue devices that may be connected in expansion mode. These 3 MSb's will address a device with the matching ID code. The address present on the RDADD bus will be selected on a rising edge of RCLK provided that RADEN is HIGH, (note, that data can be placed on to the Qout bus, read from the previously selected queue on this RCLK edge). On the next rising RCLK edge after a read queue select, a data word from the previous queue will be placed onto the outputs, Qout, regardless of the \overline{REN} input. Two RCLK rising edges after read queue select, data will be placed on to the Qout outputs from the newly selected queue, regardless of \overline{REN} due to the first word fall through effect. The second function of the RDADD bus is to select the device of queues to be loaded on to the $\overline{PAEn/PRn}$ bus during strobed flag mode. The most significant 3 bits, RDADD[5:3] are again used to select 1 of 8 possible multi-queue devices that may be connected in expansion mode. Address bits RDADD[2:0] are don't care during device selection. The device address present on the RDADD bus will be selected on the rising edge of RCLK provided that ESTR is HIGH, (note, that data can be placed on to the Qout bus, read from the previously selected Queue on this RCLK edge). Please refer to Table 2 for details on RDADD bus.
\overline{REN}	Read Enable	LVTTL INPUT	The \overline{REN} input enables read operations from a selected queue based on a rising edge of RCLK. A queue to be read from can be selected via RCLK, RADEN and the RDADD address bus regardless of the state of \overline{REN} . Data from a newly selected queue will be available on the Qout output bus on the second RCLK cycle after queue selection regardless of \overline{REN} due to the FWFT operation. A read enable is not required to cycle the $\overline{PAEn/PRn}$ bus (in polled mode) or to select the device, (in direct mode).
SCLK	Serial Clock	LVTTL INPUT	If serial programming of the multi-queue device has been selected during master reset, the SCLK input clocks the serial data through the multi-queue device. Data setup on the SI input is loaded into the device on the rising edge of SCLK provided that $\overline{SEN1}$ is enabled, LOW. When expansion of devices is performed the SCLK of all devices should be connected to the same source.
$\overline{SEN1}$	Serial Input Enable	LVTTL INPUT	During serial programming of a multi-queue device, data loaded onto the SI input will be clocked into the part (via a rising edge of SCLK), provided the $\overline{SEN1}$ input of that device is LOW. If multiple devices are cascaded, the $\overline{SEN1}$ input should be connected to the $\overline{SEN0}$ output of the previous device. So when serial loading of a given device is complete, its $\overline{SEN0}$ output goes LOW, allowing the next device in the chain to be programmed ($\overline{SEN0}$ will follow $\overline{SEN1}$ of a given device once that device is programmed). The $\overline{SEN1}$ input of the master device (or single device), should be controlled by the user.

PIN DESCRIPTIONS (CONTINUED)

Symbol	Name	I/O TYPE	Description
SEN \bar{O}	Serial Output Enable	LVTTTL OUTPUT	This output is used to indicate that serial programming or default programming of the multi-queue device has been completed. SEN \bar{O} follows SEN \bar{I} once programming of a device is complete. Therefore, SEN \bar{O} will go LOW after programming provided SEN \bar{I} is LOW, once SEN \bar{I} is taken HIGH again, SEN \bar{O} will also go HIGH. When the SEN \bar{O} output goes LOW, the device is ready to begin normal read/write operations. If multiple devices are cascaded and serial programming of the devices will be used, the SEN \bar{O} output should be connected to the SEN \bar{I} input of the next device in the chain. When serial programming of the first device is complete, SEN \bar{O} will go LOW, thereby taking the SEN \bar{I} input of the next device LOW and so on throughout the chain. When a given device in the chain is fully programmed the SEN \bar{O} output essentially follows the SEN \bar{I} input. The user should monitor the SEN \bar{O} output of the final device in the chain. When this output goes LOW, serial loading of all devices has been completed.
SI	Serial In	LVTTTL INPUT	During serial programming this pin is loaded with the serial data that will configure the multi-queue devices. Data present on SI will be loaded on a rising edge of SCLK provided that SEN \bar{I} is LOW. In expansion mode the serial data input is loaded into the first device in a chain. When that device is loaded and its SEN \bar{O} has gone LOW, the data present on SI will be directly output to the SO output. The SO pin of the first device connects to the SI pin of the second and so on. The multi-queue device setup registers are shift registers.
SO	Serial Out	LVTTTL OUTPUT	This output is used in expansion mode and allows serial data to be passed through devices in the chain to complete programming of all devices. The SI of a device connects to SO of the previous device in the chain. The SO of the final device in a chain should not be connected.
TCK ⁽²⁾	JTAG Clock	LVTTTL INPUT	Clock input for JTAG function. One of four terminals required by IEEE Standard 1149.1-1990. Test operations of the device are synchronous to TCK. Data from TMS and TDI are sampled on the rising edge of TCK and outputs change on the falling edge of TCK. If the JTAG function is not used this signal needs to be tied to GND.
TDI ⁽²⁾	JTAG Test Data Input	LVTTTL INPUT	One of four terminals required by IEEE Standard 1149.1-1990. During the JTAG boundary scan operation, test data serially loaded via the TDI on the rising edge of TCK to either the Instruction Register, ID Register and Bypass Register. An internal pull-up resistor forces TDI HIGH if left unconnected.
TDO ⁽²⁾	JTAG Test Data Output	LVTTTL OUTPUT	One of four terminals required by IEEE Standard 1149.1-1990. During the JTAG boundary scan operation, test data serially loaded output via the TDO on the falling edge of TCK from either the Instruction Register, ID Register and Bypass Register. This output is high impedance except when shifting, while in SHIFT-DR and SHIFT-IR controller states.
TMS ⁽²⁾	JTAG Mode Select	LVTTTL INPUT	TMS is a serial input pin. One of four terminals required by IEEE Standard 1149.1-1990. TMS directs the device through its TAP controller states. An internal pull-up resistor forces TMS HIGH if left unconnected.
TRST ⁽²⁾	JTAG Reset	LVTTTL INPUT	TRST is an asynchronous reset pin for the JTAG controller. The JTAG TAP controller does not automatically reset upon power-up, thus it must be reset by either this signal or by setting TMS= HIGH for five TCK cycles. If the TAP controller is not properly reset then the outputs will always be in high-impedance. If the JTAG function is used but the user does not want to use TRST, then TRST can be tied with MRS to ensure proper queue operation. If the JTAG function is not used then this signal needs to be tied to GND. An internal pull-up resistor forces TRST HIGH if left unconnected.
WADEN	Write Address Enable	LVTTTL INPUT	The WADEN input is used in conjunction with WCLK and the WRADD address bus to select a queue to be written in to. A queue addressed via the WRADD bus is selected on the rising edge of WCLK provided that WADEN is HIGH. WADEN should be asserted (HIGH) only during a queue change cycle(s). WADEN should not be permanently tied HIGH. WADEN cannot be HIGH for the same WCLK cycle as FSTR. Note, that a write queue selection cannot be made, (WADEN must NOT go active) until programming of the part has been completed and SEN \bar{O} has gone LOW.
WCLK	Write Clock	LVTTTL INPUT	When enabled by WEN, the rising edge of WCLK writes data into the selected queue via the input bus, Din. The queue to be written to is selected via the WRADD address bus and a rising edge of WCLK while WADEN is HIGH. A rising edge of WCLK in conjunction with FSTR and WRADD will also select the device to be placed on the PAFn bus during direct flag operation. During polled flag operation the PAFn bus is cycled with respect to WCLK and the FSYNC signal is synchronized to WCLK. The PAFn, PAF and FF outputs are all synchronized to WCLK. During device expansion the FXO and FXI signals are based on WCLK. The WCLK must be continuous and free-running.

PIN DESCRIPTIONS (CONTINUED)

Symbol	Name	I/O TYPE	Description
\overline{WEN}	Write Enable	LVTTL INPUT	The \overline{WEN} input enables write operations to a selected queue based on a rising edge of WCLK. A queue to be written to can be selected via WCLK, WADEN and the WRADD address bus regardless of the state of \overline{WEN} . Data present on Din can be written to a newly selected queue on the second WCLK cycle after queue selection provided that \overline{WEN} is LOW. A write enable is not required to cycle the \overline{PAF}_n bus (in polled mode) or to select the device, (in direct mode).
WRADD [4:0]	Write Address Bus	LVTTL INPUT	For the 4Q device the WRADD bus is 5 bits. The WRADD bus is a dual purpose address bus. The first function of WRADD is to select a queue to be written to. The least significant 2 bits of the bus, WRADD[1:0] are used to address 1 of 4 possible queues within a multi-queue device. The most significant 3 bits, WRADD[4:2] are used to select 1 of 8 possible multi-queue devices that may be connected in expansion mode. These 3 MSb's will address a device with the matching ID code. The address present on the WRADD bus will be selected on a rising edge of WCLK provided that WADEN is HIGH, (note, that data present on the Din bus can be written into the previously selected queue on this WCLK edge and on the next rising WCLK also, providing that \overline{WEN} is LOW). Two WCLK rising edges after write queue select, data can be written into the newly selected queue. The second function of the WRADD bus is to select the device of queues to be loaded on to the \overline{PAF}_n bus during strobed flag mode. The most significant 3 bits, WRADD[4:2] are again used to select 1 of 8 possible multi-queue devices that may be connected in expansion mode. Address bits WRADD[1:0] are don't care during device selection. The device address present on the WRADD bus will be selected on the rising edge of WCLK provided that FSTR is HIGH, (note, that data can be written into the previously selected queue on this WCLK edge). Please refer to Table 1 for details on the WRADD bus.
VCC	+3.3V Supply	Power	These are VCC power supply pins and must all be connected to a +3.3V supply rail.
GND	Ground Pin	Ground	These are Ground pins and must all be connected to the GND supply rail.

NOTES:

1. Inputs should not change after Master Reset.
2. These pins are for the JTAG port. Please refer to pages 51-55 and Figures 31-33.

ABSOLUTE MAXIMUM RATINGS

Symbol	Rating	Com'l & Ind'l	Unit
VTERM	Terminal Voltage with respect to GND	-0.5 to +4.5	V
TSTG	Storage Temperature	-55 to +125	°C
IOUT	DC Output Current	-50 to +50	mA

NOTE:

- Stresses greater than those listed under ABSOLUTE MAXIMUM RATINGS may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational sections of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect reliability.

RECOMMENDED DC OPERATING CONDITIONS

Symbol	Parameter	Min.	Typ.	Max.	Unit
VCC ⁽¹⁾	Supply Voltage (Com'l/Ind'l)	3.15	3.3	3.45	V
GND	Supply Voltage (Com'l/Ind'l)	0	0	0	V
V _{IH}	Input High Voltage (Com'l/Ind'l)	2.0	—	V _{CC} +0.3	V
V _{IL}	Input Low Voltage (Com'l/Ind'l)	—	—	0.8	V
T _A	Operating Temperature Commercial	0	—	+70	°C
T _A	Operating Temperature Industrial	-40	—	+85	°C

NOTE:

- V_{CC} = 3.3V ± 0.15V, JEDEC JESD8-A compliant.

DC ELECTRICAL CHARACTERISTICS

(Commercial: V_{CC} = 3.3V ± 0.15V, T_A = 0°C to +70°C; Industrial: V_{CC} = 3.3V ± 0.15V, T_A = 40°C to +85°C; JEDEC JESD8-A compliant)

Symbol	Parameter	Min.	Max.	Unit
I _{LI} ⁽¹⁾	Input Leakage Current	-10	10	μA
I _{LO} ⁽²⁾	Output Leakage Current	-10	10	μA
V _{OH}	Output Logic "1" Voltage, I _{OH} = -8 mA	2.4	—	V
V _{OL}	Output Logic "0" Voltage, I _{OL} = 8 mA	—	0.4	V
I _{CC1} ^(3,4,5)	Active Power Supply Current	—	100	mA
I _{CC2} ^(3,6)	Standby Current	—	25	mA

NOTES:

- Measurements with $0.4 \leq V_{IN} \leq V_{CC}$.
- $\overline{OE} \geq V_{IH}$, $0.4 \leq V_{OUT} \leq V_{CC}$.
- Tested with outputs open (I_{OUT} = 0).
- RCLK and WCLK toggle at 20 MHz and data inputs switch at 10 MHz.
- Typical I_{CC1} = 16 + 3.14*fs + 0.02*CL*fs (in mA) with V_{CC} = 3.3V, T_A = 25°C, fs = WCLK frequency = RCLK frequency (in MHz, using TTL levels), data switching at fs/2, CL = capacitive load (in pF).
- RCLK and WCLK, toggle at 20 MHz.
The following inputs should be pulled to GND: WRADD, RDADD, WADEN, RADEN, FSTR, ESTR, SCLK, SI, EXI, FXI and all Data Inputs.
The following inputs should be pulled to V_{CC}: \overline{WEN} , \overline{REN} , \overline{SEN} , \overline{PRS} , \overline{MRS} , TDI, TMS and \overline{TRST} .
All other inputs are don't care, and should be pulled HIGH or LOW.

CAPACITANCE (T_A = +25°C, f = 1.0MHz)

Symbol	Parameter ⁽¹⁾	Conditions	Max.	Unit
C _{IN} ⁽²⁾	Input Capacitance	V _{IN} = 0V	10	pF
C _{OUT} ^(1,2)	Output Capacitance	V _{OUT} = 0V	10	pF

NOTES:

- With output deselected, ($\overline{OE} \geq V_{IH}$).
- Characterized values, not currently tested.

FUNCTIONAL DESCRIPTION

MASTER RESET

A Master Reset is performed by toggling the \overline{MRS} input from HIGH to LOW to HIGH. During a master reset all internal multi-queue device setup and control registers are initialized and require programming either serially by the user via the serial port, or using the default settings. During a master reset the state of the following inputs determine the functionality of the part, these pins should be held HIGH or LOW.

PKT – Packet Mode
FM – Flag bus Mode
IW, OW, BM – Bus Matching options
MAST – Master Device
ID0, 1, 2 – Device ID

DFM – Programming mode, serial or default
DF – Offset value for \overline{PAE} and \overline{PAF}

Once a master reset has taken place, the device must be programmed either serially or via the default method before any read/write operations can begin.

See Figure 4, *Master Reset* for relevant timing.

PARTIAL RESET

A Partial Reset is a means by which the user can reset both the read and write pointers of a single queue that has been setup within a multi-queue device. Before a partial reset can take place on a queue, the respective queue must be selected on both the read port and write port a minimum of 2 RCLK and 2 WCLK cycles before the \overline{PRS} goes LOW. The partial reset is then performed by toggling the \overline{PRS} input from HIGH to LOW to HIGH, maintaining the LOW state for at least one WCLK and one RCLK cycle. Once a partial reset has taken place a minimum of 3 WCLK and 3 RCLK cycles must occur before enabled writes or reads can occur.

A Partial Reset only resets the read and write pointers of a given queue, a partial reset will not effect the overall configuration and setup of the multi-queue device and its queues.

See Figure 5, *Partial Reset* for relevant timing.

SERIAL PROGRAMMING

The multi-queue flow-control device is a fully programmable device, providing the user with flexibility in how queues are configured in terms of the number of queues, depth of each queue and position of the \overline{PAF} / \overline{PAE} flags within respective queues. All user programming is done via the serial port after a master reset has taken place. Internally the multi-queue device has setup registers which must be serially loaded, these registers contain values for every queue within the device, such as the depth and \overline{PAE} / \overline{PAF} offset values. The IDT72V51236/72V51246/72V51256 devices are capable of up to 4 queues and therefore contain 4 sets of registers for the setup of each queue.

During a Master Reset if the DFM (Default Mode) input is LOW, then the device will require serial programming by the user. It is recommended that the user utilize a 'C' program provided by IDT, this program will prompt the user for all information regarding the multi-queue setup. The program will then generate a serial bit stream which should be serially loaded into the device via the serial port. For the IDT72V51236/72V51246/72V51256 devices the serial programming requires a total number of serially loaded bits per device, (SCLK cycles with \overline{SEN} enabled), calculated by: $19+(Q \times 72)$ where Q is the number of queues the user wishes to setup within the device. Please refer to the separate Application Note, AN-303 for recommended control of the serial programming port.

Once the master reset is complete and \overline{MRS} is HIGH, the device can be serially loaded. Data present on the SI (serial in), input is loaded into the serial

port on a rising edge of SCLK (serial clock), provided that \overline{SEN} (serial in enable), is LOW. Once serial programming of the device has been successfully completed the device will indicate this via the \overline{SEN} (serial output enable) going active, LOW. Upon detection of completion of programming, the user should cease all programming and take \overline{SEN} inactive, HIGH. Note, \overline{SEN} follows \overline{SEN} once programming of a device is complete. Therefore, \overline{SEN} will go LOW after programming provided \overline{SEN} is LOW, once \overline{SEN} is taken HIGH again, \overline{SEN} will also go HIGH. The operation of the SO output is similar, when programming of a given device is complete, the SO output will follow the SI input.

If devices are being used in expansion mode the serial ports of devices should be cascaded. The user can load all devices via the serial input port control pins, SI & \overline{SEN} , of the first device in the chain. Again, the user may utilize the 'C' program to generate the serial bit stream, the program prompting the user for the number of devices to be programmed. The \overline{SEN} and SO (serial out) of the first device should be connected to the \overline{SEN} and SI inputs of the second device respectively and so on, with the \overline{SEN} & SO outputs connecting to the \overline{SEN} & SI inputs of all devices through the chain. All devices in the chain should be connected to a common SCLK. The serial output port of the final device should be monitored by the user. When \overline{SEN} of the final device goes LOW, this indicates that serial programming of all devices has been successfully completed. Upon detection of completion of programming, the user should cease all programming and take \overline{SEN} of the first device in the chain inactive, HIGH.

As mentioned, the first device in the chain has its serial input port controlled by the user, this is the first device to have its internal registers serially loaded by the serial bit stream. When programming of this device is complete it will take its \overline{SEN} output LOW and bypass the serial data loaded on the SI input to its SO output. The serial input of the second device in the chain is now loaded with the data from the SO of the first device, while the second device has its \overline{SEN} input LOW. This process continues through the chain until all devices are programmed and the \overline{SEN} of the final device goes LOW.

Once all serial programming has been successfully completed, normal operations, (queue selections on the read and write ports) may begin. When connected in expansion mode, the IDT72V51236/72V51246/72V51256 devices require a total number of serially loaded bits per device to complete serial programming, (SCLK cycles with \overline{SEN} enabled), calculated by: $n[19+(Q \times 72)]$ where Q is the number of queues the user wishes to setup within the device, where n is the number of devices in the chain.

See Figure 6, *Serial Port Connection* and Figure 7, *Serial Programming for connection and timing information.*

DEFAULT PROGRAMMING

During a Master Reset if the DFM (Default Mode) input is HIGH the multi-queue device will be configured for default programming, (serial programming is not permitted). Default programming provides the user with a simpler, however limited means by which to setup the multi-queue flow-control device, rather than using the serial programming method. The default mode will configure a multi-queue device such that the maximum number of queues possible are setup, with all of the parts available memory blocks being allocated equally between the queues. The values of the \overline{PAE} / \overline{PAF} offsets is determined by the state of the DF (default) pin during a master reset.

For the IDT72V51236/72V51246/72V51256 devices the default mode will setup 4 queues, each queue being 4,096 x 36, 8,192 x 36 and 16,384 x 36 deep respectively. For both devices the value of the \overline{PAE} / \overline{PAF} offsets is determined at master reset by the state of the DF input. If DF is LOW then both the \overline{PAE} & \overline{PAF} offset will be 8, if HIGH then the value is 128.

When configuring the IDT72V51236/72V51246/72V51256 devices in default mode the user simply has to apply WCLK cycles after a master reset, until \overline{SEN} goes LOW, this signals that default programming is complete. These clock

cycles are required for the device to load its internal setup registers. When a single multi-queue is used, the completion of device programming is signaled by the $\overline{\text{SENO}}$ output of a device going from HIGH to LOW. Note, that $\overline{\text{SENI}}$ must be held LOW when a device is setup for default programming mode.

When multi-queue devices are connected in expansion mode, the $\overline{\text{SENI}}$ of the first device in a chain can be held LOW. The $\overline{\text{SENO}}$ of a device should connect to the $\overline{\text{SENI}}$ of the next device in the chain. The $\overline{\text{SENO}}$ of the final device is used to indicate that default programming of all devices is complete. When the final $\overline{\text{SENO}}$ goes LOW normal operations may begin. Again, all devices will be programmed with their maximum number of queues and the memory divided equally between them. Please refer to Figure 8, *Default Programming*.

READING AND WRITING TO THE IDT MULTI-QUEUE FLOW-CONTROL DEVICE

The IDT72V51236/72V51346/72V51256 multi-queue flow-control devices can be configured in two distinct modes, namely Standard Mode and Packet Mode.

STANDARD MODE OPERATION (PKT = LOW on Master Reset)

WRITE QUEUE SELECTION AND WRITE OPERATION (STANDARD MODE)

The IDT72V51236/72V51346/72V51256 multi-queue flow-control devices can be configured up to a maximum of 4 queues into which data can be written via a common write port using the data inputs (Din), write clock (WCLK) and write enable ($\overline{\text{WEN}}$). The queue to be written is selected by the address present on the write address bus (WRADD) during a rising edge on WCLK

while write address enable (WADEN) is HIGH. The state of $\overline{\text{WEN}}$ does not impact the queue selection. The queue selection is requires 2 WCLK cycles. All subsequent data writes will be to this queue until another queue is selected.

Standard mode operation is defined as individual words will be written to the device as opposed to Packet Mode where complete packets may be written. The write port is designed such that 100% bus utilization can be obtained. This means that data can be written into the device on every WCLK rising edge including the cycle that a new queue is being addressed.

Changing queues requires a minimum of 2 WCLK cycles on the write port (see Figure 9, *Write Queue Select, Write Operation and Full flag Operation*). WADEN goes high signaling a change of queue (clock cycle "A"). The address on WRADD at that time determines the next queue. Data presented during that cycle ("A") and the next cycle ("B"), will be written to the active (old) queue, provided $\overline{\text{WEN}}$ is active LOW. If $\overline{\text{WEN}}$ is HIGH (inactive) for these two clock cycles, data will not be written in to the previous queue. The write port discrete full flag will update to show the full status of the newly selected queue (Q_x) at this last cycle's rising edge ("B"). Data present on the data input bus (Din), can be written into the newly selected queue (Q_x) on the rising edge of WCLK on the second cycle ("C") following a change of queue, provided $\overline{\text{WEN}}$ is LOW and the new queue is not full. If the newly selected queue is full at the point of its selection, any writes to that queue will be prevented. Data cannot be written into a full queue.

Refer to Figure 9, *Write Queue Select, Write Operation and Full flag Operation*, Figure 10, *Write Operations & First Word Fall Through* for timing diagrams and Figure 11, *Full Flag Timing in Expansion Mode* for timing diagrams.

TABLE 1 — WRITE ADDRESS BUS, WRADD[4:0]

Operation	WCLK	WADEN	FSTR	WRADD[4:0]	
Write Queue Select		1	0	4 3 2 Device Select (Compared to ID0,1,2)	1 0 Write Queue Address (2 bits = 4 Queues)
$\overline{\text{PAFn}}$ Flag Bus Device Select		0	1	4 3 2 Device Select (Compared to ID0,1,2)	1 0 X X

5937 drw05

READ QUEUE SELECTION AND READ OPERATION (STANDARD MODE)

The IDT72V51236/72V51346/72V51256 multi-queue flow-control devices can be configured up to a maximum of 4 queues which data can be read via a common read port using the data outputs (Qout), read clock (RCLK) and read enable (REN). An output enable, OE control pin is also provided to allow High-Impedance selection of the Qout data outputs. The multi-queue device read port operates in a mode similar to “First Word Fall Through” on a SuperSync IDT FIFO, but with the added feature of data output pipelining (see Figure 10, *Write Operations & First Word Fall Through*). The queue to be read is selected by the address presented on the read address bus (RDADD) during a rising edge on RCLK while read address enable (RADEN) is HIGH. The state of REN does not impact the queue selection. The queue selection requires 2 RCLK cycles. All subsequent data reads will be from this queue until another queue is selected.

Standard mode operation is defined as individual words will be read from the device as opposed to Packet Mode where complete packets may be read. The read port is designed such that 100% bus utilization can be obtained. This means that data can be read out of the device on every RCLK rising edge including the cycle that a new queue is being addressed.

Changing queues requires a minimum of two RCLK cycles on the read port (see Figure 12, *Read Queue Select, Read Operation*). RADEN goes high signaling a change of queue (clock cycle “D”). The address on RDADD at that time determines the next queue. Data presented during that cycle (“D”) will be read at “D” (+t_A), can be read from the active (old) queue (Q_p), provided REN is active LOW. If REN is HIGH (inactive) for this clock cycle, data will not be read from the previous queue. The next cycle’s rising edge (“E”), the read port discrete empty flag will update to show the empty status of the newly selected

queue (Q_F). The internal pipeline is also loaded at this time (“D”) with the last word from the previous (old) queue (Q_p) as well as the next word from the new queue (Q_F). Both of these words will fall through to the output register (provided the OE is asserted) consecutively (cycles “E” and “F” respectively) following the selection of the new queue regardless of the state of REN, unless the new queue (Q_F) is empty. If the newly selected queue is empty, any reads from that queue will be prevented. Data cannot be read from an empty queue. The last word in the data output register (from the previous queue), will remain on the data bus, but the output valid flag, OV will go HIGH, to indicate that the data present is no longer valid. This pipelining effect provides the user with 100% bus utilization, and brings about the possibility that a “NULL” queue may be required within a multi-queue device. Null queue operation is discussed in the next section. Remember that OE allows the user to place the data output bus (Qout) into High-Impedance and the data can be read in to the output register regardless of OE.

Refer to Table 2, for Read Address Bus arrangement. Also, refer to Figures 12, 14, and 15 for read queue selection and read port operation timing diagrams.

PACKET MODE OPERATION (PKT = HIGH on Master Reset)

The Packet mode operation provides the capability where, user defined packets or frames can be written to the device as opposed to Standard mode where individual words are written. For clarification, in Packet Mode, a packet can be written to the device with the starting location designated as Transmit Start of Packet (TSOP) and the ending location designated as Transmit End of Packet (TEOP). In conjunction, a packet read from the device will be designated as Receive Start of Packet (RSOP) and a Receive End of Packet

TABLE 2 — READ ADDRESS BUS, RDADD[5:0]

Operation	RCLK	RADEN	ESTR	RDADD[5:0]		
Read Queue Select		1	0	5 4 3 Device Select (Compared to ID0,1,2)	2 Null-Q Select Pin	1 0 Read Queue Address (2 bits = 4 Queues)
Flag Bus Device Selection		0	1	5 4 3 Device Select (Compared to ID0,1,2)	2 X	1 0 X X

5937 drw06

(REOP). The minimum size for a packet is four words (SOP, two words of data and EOP). The almost empty flag bus becomes the "Packet Ready" \overline{PR} flag bus when the device is configured for packet mode. Valid packets are indicated when both \overline{PR} and \overline{OV} are asserted.

WRITE QUEUE SELECTION AND WRITE OPERATION (PACKET MODE)

It is required that a full packet be written to a queue before moving to a different queue. The device requires two cycles to change queues. Packet mode, has 2 restrictions: <1> An extra word (or filler word) is required to be written after each packet on the cycle following the queue change to ensure the RSOP in the old queue is not read out on a queue change because of the first word fall through. <2> No SOP/EOP is allowed to read/written at cycle ("C" or "I") the next cycle after a queue change. For clock frequency (fs) of 133MHz and below see Application Note AN-398. In this mode, the write port may not obtain 100% bus utilization

Changing queues requires a minimum of two WCLK cycles on the write port (see Figure 16, *Writing in Packet Mode during a Queue Change*). WADEN goes high signaling a change of queue (clock cycle "B" or "H"). The address on WRADD at the rising edge of WCLK determines the next queue. Data presented on Din during that cycle ("B" or "H") can continue to be written to the active (old) queue (Q_A or Q_B respectively), provided \overline{WEN} is LOW (active). If \overline{WEN} is HIGH (inactive) for this clock cycle (H), data will not be written in to the previous queue (Q_B). The cycle following a request for queue change ("C" or "I") will require a filler word to be written to the device. This can be done by clocking the TEOP twice or by writing a filler word. In packet mode, the multi-queue is designed under the 2 restrictions listed previously. Note, an erroneous Packet Ready flag may occur if the EOP or SOP marker shows up at the next cycle after a queue change. To prevent an erroneous Packet Ready flag from occurring a filler word should be written into the old queue at the last clock cycle of writing. It is important to know that no SOP or EOP may be written into the device during this cycle ("C" or "I"). The write port discrete full flag will update to show the full status of the newly selected queue (Q_B) at this last cycle's rising edge ("C" or "I"). Data values presented on the data input bus (Din), can be written into the newly selected queue (Q_x) on the rising edge of WCLK on the second cycle ("D" or "J") following a request for change of queue, provided \overline{WEN} is LOW (active) and the new queue is not full. If a selected queue is full (\overline{FF} is LOW), then writes to that queue will be prevented. Note, data cannot be written into a full queue.

Refer to Figure 16, *Writing in Packet Mode during a Queue Change* and Figure 18, *Data Input (Transit) packet mode of Operation* for timing diagrams.

READ QUEUE SELECTION AND READ OPERATION (PACKET MODE)

In Packet Mode it is required that a full packet is read from a queue before moving to a different queue. The device requires two cycles to change queues. In Packet Mode, there are 2 restrictions <1> An extra word (or filler word) should have been inserted into the data stream after each packet to insure the RSOP in the old queue is not read out on a queue change because of the first word fall through and this word should be discarded. <2> No EOP/SOP is allowed to be read/written at cycle ("C" or "I") the next cycle after a queue change. For clock frequency of 133Mhz and below see Application Note AN-398. In this mode, the read port may not obtain 100% bus utilization

Changing queues requires a minimum of two RCLK cycles on the read port (see Figure 17, *Reading in Packet Mode during a Queue Change*). RADEN goes high signaling a change of queue (clock cycle "B" or "I"). The address on RDADD at the rising edge of RCLK determines the queue. As illustrated in Figure 17 during cycle ("B"), data can be read from the active (old) queue (Q_A), provided both \overline{REN} and \overline{OE} are LOW (active) simultaneously with changing queues. REOP for packet located in queue (Q_A) must be read before

a queue change request is made ("B"). If \overline{REN} is HIGH (inactive) for this clock cycle ("I"), data will not be read from the previous queue (Q_B). In applications where the multi-queue flow-control device is connected to a shared bus, an output enable, \overline{OE} control pin is also provided to allow High-Impedance selection of the data outputs (Q_{out}). With reference to Figure 17 when changing queues, a packet marker (SOP or EOP) should not be read on cycle ("C" or "I"). Reading a SOP or EOP should not occur during the cycles required for a queue change. It is also recommended that a queue change should not occur once the reading of the packet has commenced. The EOP marker of the packet prior to a queue change should be read on or before the queue change. If the EOP word is read before a queue change, \overline{REN} can be pulled high to disable further reads. When the queue change is initiated, the filler word written into the current queue after the EOP word will fall through followed by and the first word from the new queue.

Refer to Figure 17, *Reading in Packet Mode during a Queue Change* as well as Figures 12, 14, and 15 for timing diagrams and Table 2, for Read Address bus arrangement.

Note, the almost empty flag bus becomes the "Packet Ready" flag bus when the device is configured for packet mode.

PACKET READY FLAG

The multi-queue flow-control device provides the user with a Packet Ready feature. During a Master Reset the logic "1" (HIGH) on the PKT input signal (packet mode select), configures the device in packet mode. The \overline{PR} discrete flag, provides a packet ready status of the active queue selected on the read port. A packet ready status is individually maintained on all queues; however only the queue selected on the read port has its packet ready status indicated on the \overline{PR} output flag. A packet is available on the output for reading when both \overline{PR} and \overline{OV} are asserted LOW. If less than a full packet is available, the \overline{PR} flag will be HIGH (packet not ready). In packet mode, no words can be read from a queue until a complete packet has been written into that queue, regardless of \overline{REN} .

When packet mode is selected the Programmable Almost Empty bus, \overline{PAEn} , becomes the Packet Ready bus, \overline{PRn} . When configured in Direct Bus (FM = LOW during a master reset), the \overline{PRn} bus provides packet ready status in 8 queue increments. The \overline{PRn} bus supports either Polled or Direct modes of operation. The \overline{PRn} mode of operation is configured through the Flag Mode (FM) bit during a Master Reset.

When the multi-queue is configured for packet mode operation, the device must also be configured for 36 bit write data bus and 36 bit read data bus. The two most significant bits of the 36-bit data bus are used as "packet markers". On the write port these are bits D34 (Transmit Start of Packet,) D35 (Transmit End of Packet) and on the read port Q34, Q35. All four bits are monitored by the packet control logic as data is written into and read out from the queues. The packet ready status for individual queues is then determined by the packet ready logic.

On the write port D34 is used to "mark" the first word being written into the selected queue as the "Transmit Start of Packet", TSOP. To further clarify, when the user requires a word being written to be marked as the start of a packet, the TSOP input (D34) must be HIGH for the same WCLK rising edge as the word that is written. The TSOP marker is stored in the queue along with the data it was written in until the word is read out of the queue via the read port.

On the write port D35 is used to "mark" the last word of the packet currently being written into the selected queue as the "Transmit End of Packet" TEOP. When the user requires a word being written to be marked as the end of a packet, the TEOP input must be HIGH for the same WCLK rising edge as the word that is written in. The TEOP marker is stored in the queue along with the data it was written in until the word is read out of the queue via the read port.

TABLE 5 — PACKET MODE VALID BYTE

D35/Q35	D34/Q34	D33/Q33	D32/Q32	D31/Q31	D23/Q23	D15/Q15	D7/Q7	D0/Q0
EOP	SOP	MOD 1	MOD 2	BYTE D	BYTE C	BYTE B	BYTE A

0	0	A, B, C, D
0	1	A
1	0	A, B
1	1	A, B, C

5937 drw07

NOTE:

Packet Mode is only available when the Input Port and Output Port are 36 bits wide.

The packet ready logic monitors all start and end of packet markers both as they enter respective queues via the write port and as they exit queues via the read port. The multi-queue internal logic increments and decrements a packet counter, which is provided for each queue. The functionality of the packet ready logic provides status as to whether at least one full packet of data is available within the selected queue. A partial packet in a queue is regarded as a packet not ready and \overline{PR} (active LOW) will be HIGH. In Packet mode, no words can be read from a queue until at least one complete packet has been written into the queue, regardless of \overline{REN} . For example, if a TSOP has been written and some number of words later a TEOP is written a full packet of data is deemed to be available, and the \overline{PR} flag and \overline{OV} will go active LOW. Consequently if reads begin from a queue that has only one complete packet and the RSOP is detected on the output port as data is being read out, \overline{PR} will go inactive HIGH. \overline{OV} will remain LOW indicating there is still valid data being read out of that queue until the REOP is read. The user may proceed with the reading operation until the current packet has been read out and no further complete packets are available. If during that time another complete packet has been written into the queue and the \overline{PR} flag will again go active, then reads from the new packet may follow after the current packet has been completely read out.

The packet counters therefore look for start of packet markers followed by end of packet markers and regard data in between the TSOP and TEOP as a full packet of data. The packet monitoring has no limitation as to how many packets are written into a queue, the only constraint is the depth of the queue. Note, there is a minimum allowable packet size of four words, inclusive of the TSOP marker and TEOP marker.

The packet logic does expect a TSOP marker to be followed by a TEOP marker.

If a second TSOP marker is written after a first, it is ignored and the logic regards data between the first TSOP and the first subsequent TEOP as the full packet. The same is true for TEOP; a second consecutive TEOP mark is ignored. On the read side the user should regard a packet as being between the first RSOP and the first subsequent REOP and disregard consecutive RSOP markers and/or REOP markers. This is why a TEOP may be written twice, using the second TEOP as the filler word.

As an example, the user may also wish to implement the use of an “Almost End of Packet”(AEOP) marker. For example, the AEOP can be assigned to data input bit D33. The purpose of this AEOP marker is to provide an indicator

that the end of packet is a fixed (known) number of reads away from the end of packet. This is a useful feature when due to latencies within the system, monitoring the REOP marker alone does not prevent “over reading” of the data from the queue selected. For example, an AEOP marker set 4 writes before the TEOP marker provides the device connected to the read port with an “almost end of packet” indication 4 cycles before the end of packet.

The AEOP can be set any number of words before the end of packet determined by user requirements or latencies involved in the system.

See Figure 17, *Reading in Packet Mode during a Queue Change*, Figure 18, *Data Input (Transmit) Packet Mode of Operation* and Figure 19, *Data Output (Receive) Packet Mode of Operation*.

PACKET MODE – MODULO OPERATION

The internal packet ready control logic performs no operation on these modulo bits, they are only informational bits that are passed through with the respective data byte(s).

When utilizing the multi-queue flow-control device in packet mode, the user may also want to consider the implementation of “Modulo” operation or “valid byte marking”. Modulo operation may be useful when the packets being transferred through a queue are in a specific byte arrangement even though the data bus width is 36 bits. In Modulo operation the user can concatenate bytes to form a specific data string through the multi-queue device. A possible scenario is where a limited number of bytes are extracted from the packet for either analysis or filtered for security protection. This will only occur when the first 36 bit word of a packet is written in and the last 36 bit word of packet is written in. The modulo operation is a means by which the user can mark and identify specific data within the Queue.

On the write port data input bits, D32 (transmit modulo bit 2, TMOD2) and D33 (transmit modulo bit 1, TMOD1) can be used as data markers. An example of this could be to use D32 and D33 to code which bytes of a word are part of the packet that is also being marked as the “Start of Marker” or “End of Marker”. Conversely on the read port when reading out these marked words, data outputs Q32 (receive modulo bit 2, RMOD2) and Q33 (receive modulo bit 1, RMOD1) will pass on the byte validity information for that word. Refer to Table 5 for one example of how the modulo bits may be setup and used. See Figure 18, *Data Input (Transmit) Packet Mode of Operation* and Figure 19, *Data Output (Receive) Packet Mode of Operation*.

NULL QUEUE OPERATION (OF THE READ PORT)

Pipelining of data to the output port enables the device to provide 100% bus utilization in standard mode. Data can be read out of the multi-queue flow-control device on every RCLK cycle regardless of queue switches or other operations. The device architecture is such that the pipeline is constantly filled with the next words in a selected queue to be read out, again providing 100% bus utilization. This type of architecture does assume that the user is constantly switching queues such that during a queue switch, the last data word required from the previous queue will fall through the pipeline to the output.

Note, that if reads cease at the empty boundary of a queue, then the last word will automatically flow through the pipeline to the output.

The Null-Q is selected via read port address space RDADD[2]. The RDADD[5:0] bus should be addressed with xxx1xx, this address is the Null-Q. A null queue can be selected when no further reads are required from a previously selected queue. Changing to a null queue will continue to propagate data in the pipeline to the previous queue's output. The Null Q can remain selected until a data becomes available in another queue for reading. The Null-Q can be utilized in either standard or packet mode.

Note: If the user switches the read port to the null queue, this queue is seen as and treated as an empty queue, therefore after switching to the null queue the last word from the previous queue will remain in the output register and the \overline{OV} flag will go HIGH, indicating data is not valid.

The Null queue operation only has significance to the read port of the multi-queue, it is a means to force data through the pipeline to the output. Null Q selection and operation has no meaning on the write port of the device. Also, refer to Figure 20, *Read Operation and Null Queue Select* for diagram.

PAF_n FLAG BUS OPERATION

The IDT72V51236/72V51246/72V51256 multi-queue flow-control devices can be configured for up to 4 queues, each queue having its own almost full status. An active queue has its flag status output to the discrete flags, \overline{FF} and \overline{PAF} , on the write port. Queues that are not selected for a write operation can have their \overline{PAF} status monitored via the \overline{PAF}_n bus. The \overline{PAF}_n flag bus is 4 bits wide, so that all 4 queues can have their status output to the bus. When a single multi-queue device is used anywhere from 1 to 4 queues may be set-up within the part, each queue having its own dedicated \overline{PAF} flag output on the \overline{PAF}_n bus. Queues 1 through 4 have their \overline{PAF} status to $\overline{PAF}[0]$ through $\overline{PAF}[3]$ respectively. If less than 4 queues are used then only the associated \overline{PAF}_n outputs will be required, unused \overline{PAF}_n outputs will be don't care outputs. When devices are connected in expansion mode the \overline{PAF}_n flag bus can also be expanded beyond 4 bits to produce a wider \overline{PAF}_n bus that encompasses all queues.

Alternatively, the 4 bit \overline{PAF}_n flag bus of each device can be connected together to form a single 4 bit bus, i.e. $\overline{PAF}[0]$ of device 1 will connect to $\overline{PAF}[0]$ of device 2 etc. When connecting devices in this manner the \overline{PAF}_n can only be driven by a single device at any time, (the \overline{PAF}_n outputs of all other devices must be in high impedance state). There are two methods by which the user can select which device has control of the bus, these are "Direct" (Addressed) mode or "Polled" (Looped) mode, determined by the state of the FM (flag Mode) input during a Master Reset.

EXPANDING UP TO 32 QUEUES OR PROVIDING DEEPER QUEUES

Expansion can take place using either the standard mode or the packet mode. In the 4 queue multi-queue device, the WRADD address bus is 5 bits wide. The 2 Least Significant bits (LSBs) are used to address one of the 4 available queues within a single multi-queue device. The 3 Most Significant bits (MSBs) are used when a device is connected in expansion mode with up to 8 devices connected in width expansion, each device having its own 3-bit

address. When logically expanded with multiple parts, each device is statically setup with a unique chip ID code on the ID pins, ID0, ID1, and ID2. A device is selected when the 3 Most Significant bits of the WRADD address bus matches a 3-bit ID code. The maximum logical expansion is 32 queues (4 queues x 8 devices) or a minimum of 8 queues (1 queue per device x 8 devices), each of the maximum size of the individual memory device.

Note: The WRADD bus is also used in conjunction with FSTR (almost full flag bus strobe), to address the almost full flag bus during direct mode of operation.

Refer to Table 1, for Write Address bus arrangement. Also, refer to Figure 11, *Full Flag Timing Expansion Mode*, Figure 13, *Output Valid Flag Timing (In Expansion Mode)*, and Figure 30, *Multi-Queue Expansion Diagram*, for timing diagrams.

BUS MATCHING OPERATION

Bus Matching operation between the input port and output port is available. During a master reset of the multi-queue the state of the three setup pins, BM (Bus Matching), IW (Input Width) and OW (Output Width) determine the input and output port bus widths as per the selections shown in Table 3, "Bus Matching Set-up". 9 bit bytes, 18 bit words and 36 bit long words can be written into and read from the queues provided that at least one of the ports is setup for x36 operation. When writing to or reading from the multi-queue in a bus matching mode, the device orders data in a "Little Endian" format. See Figure 3, *Bus Matching Byte Arrangement* for details.

The Full flag and Almost Full flag operation is always based on writes and reads of data widths determined by the write port width. For example, if the input port is x36 and the output port is x9, then four data reads from a full queue will be required to cause the full flag to go HIGH (queue not full). Conversely, the Output Valid flag and Almost Empty flag operations are always based on writes and reads of data widths determined by the read port. For example, if the input port is x18 and the output port is x36, two write operations will be required to cause the output valid flag of an empty queue to go LOW, output valid (queue is not empty).

Note, that the input port serves all queues within a device, as does the output port, therefore the input bus width to all queues is equal (determined by the input port size) and the output bus width from all queues is equal (determined by the output port size).

TABLE 3 — BUS-MATCHING SET-UP

BM	IW	OW	Write Port	Read Port
0	X	X	x36	x36
1	0	0	x36	x18
1	0	1	x36	x9
1	1	0	x18	x36
1	1	1	x9	x36

FULL FLAG OPERATION

The multi-queue flow-control device provides a single Full Flag output, \overline{FF} . The \overline{FF} flag output provides a full status of the queue currently selected on the write port for write operations. Internally the multi-queue flow-control device monitors and maintains a status of the full condition of all queues within it, however only the queue that is selected for write operations has its full status output to the \overline{FF} flag. This dedicated flag is often referred to as the "active queue full flag".

When queue switches are being made on the write port, the \overline{FF} flag output will switch to the new queue and provide the user with the new queue status, on the cycle after a new queue selection is made. The user then has a full status

for the new queue one cycle ahead of the WCLK rising edge that data can be written into the new queue. That is, a new queue can be selected on the write port via the WRADD bus, WADEN enable and a rising edge of WCLK. On the next rising edge of WCLK, the \overline{FF} flag output will show the full status of the newly selected queue. On the second rising edge of WCLK following the queue selection, data can be written into the newly selected queue provided that data and enable setup & hold times are met.

Note, the \overline{FF} flag will provide status of a newly selected queue one WCLK cycle after queue selection, which is one cycle before data can be written to that queue. This prevents the user from writing data to a queue that is full, (assuming that a queue switch has been made to a queue that is actually full).

The \overline{FF} flag is synchronous to the WCLK and all transitions of the \overline{FF} flag occur based on a rising edge of WCLK. Internally the multi-queue device monitors and keeps a record of the full status for all queues. It is possible that the status of a \overline{FF} flag may be changing internally even though that flag is not the active queue flag (selected on the write port). A queue selected on the read port may experience a change of its internal full flag status based on read operations.

See Figure 9, *Write Queue Select, Write Operation and Full Flag Operation* and Figure 11, *Full Flag Timing in Expansion Mode* for timing information.

EXPANSION MODE - FULL FLAG OPERATION

When multi-queue devices are connected in Expansion mode the \overline{FF} flags of all devices should be connected together, such that a system controller monitoring and managing the multi-queue devices write port only looks at a single \overline{FF} flag (as opposed to a discrete \overline{FF} flag for each device). This \overline{FF} flag is only pertinent to the queue being selected for write operations at that time. Remember, that when in expansion mode only one multi-queue device can be written to at any moment in time, thus the \overline{FF} flag provides status of the active queue on the write port.

This connection of flag outputs to create a single flag requires that the \overline{FF} flag output have a High-Impedance capability, such that when a queue selection is made only a single device drives the \overline{FF} flag bus and all other \overline{FF} flag outputs connected to the \overline{FF} flag bus are placed into High-Impedance. The user does not have to select this High-Impedance state, a given multi-queue flow-control device will automatically place its \overline{FF} flag output into High-Impedance when none of its queues are selected for write operations.

When queues within a single device are selected for write operations, the \overline{FF} flag output of that device will maintain control of the \overline{FF} flag bus. Its \overline{FF} flag will simply update between queue switches to show the respective queue full status.

The multi-queue device places its \overline{FF} flag output into High-Impedance based on the 3 bit ID code found in the 3 most significant bits of the write queue address bus, WRADD. If the 3 most significant bits of WRADD match the 3 bit ID code setup on the static inputs, ID0, ID1 and ID2 then the \overline{FF} flag output of the respective device will be in a Low-Impedance state. If they do not match, then the \overline{FF} flag output of the respective device will be in a High-Impedance state. See Figure 11, *Full Flag Timing in Expansion Mode* for details of flag operation, including when more than one device is connected in expansion.

OUTPUT VALID FLAG OPERATION

The multi-queue flow-control device provides a single Output Valid flag output, \overline{OV} . The \overline{OV} provides an empty status or data output valid status for the data word currently available on the output register of the read port. The rising edge of an RCLK cycle that places new data onto the output register of the read port, also updates the \overline{OV} flag to show whether or not that new data word is actually valid. Internally the multi-queue flow-control monitors and maintains a status of the empty condition of all queues within it, however only the queue that is selected for read operations has its output valid (empty) status output to the \overline{OV} flag, giving a valid status for the word being read at that time.

The nature of the first word fall through operation means that when the last data word is read from a selected queue, the \overline{OV} flag will go HIGH on the next enabled read, that is, on the next rising edge of RCLK while \overline{REN} is LOW.

When queue switches are being made on the read port, the \overline{OV} flag will switch to show status of the new queue in line with the data output from the new queue. When a queue selection is made the first data from that queue will appear on the Qout data outputs 2 RCLK cycles later, the \overline{OV} will change state to indicate validity of the data from the newly selected queue on this 2nd RCLK cycle also. The previous cycles will continue to output data from the previous queue and the \overline{OV} flag will indicate the status of those outputs. Again, the \overline{OV} flag always indicates status for the data currently present on the output register.

The \overline{OV} flag is synchronous to the RCLK and all transitions of the \overline{OV} flag occur based on a rising edge of RCLK. Internally the multi-queue device monitors and keeps a record of the output valid (empty) status for all queues. It is possible that the status of an \overline{OV} flag may be changing internally even though that respective flag is not the active queue flag (selected on the read port). A queue selected on the write port may experience a change of its internal \overline{OV} flag status based on write operations, that is, data may be written into that queue causing it to become "not empty".

See Figure 12, *Read Queue Select, Read Operation* and Figure 13, *Output Valid Flag Timing* for details of the timing.

EXPANSION MODE – OUTPUT VALID FLAG OPERATION

When multi-queue devices are connected in Expansion mode, the \overline{OV} flags of all devices should be connected together, such that a system controller monitoring and managing the multi-queue devices read port only looks at a single \overline{OV} flag (as opposed to a discrete \overline{OV} flag for each device). This \overline{OV} flag is only pertinent to the queue being selected for read operations at that time. Remember, that when in expansion mode only one multi-queue device can be read from at any moment in time, thus the \overline{OV} flag provides status of the active queue on the read port.

This connection of flag outputs to create a single flag requires that the \overline{OV} flag output have a High-Impedance capability, such that when a queue selection is made only a single device drives the \overline{OV} flag bus and all other \overline{OV} flag outputs connected to the \overline{OV} flag bus are placed into High-Impedance. The user does not have to select this High-Impedance state, a given multi-queue flow-control device will automatically place its \overline{OV} flag output into High-Impedance when none of its queues are selected for read operations.

When queues within a single device are selected for read operations, the \overline{OV} flag output of that device will maintain control of the \overline{OV} flag bus. Its \overline{OV} flag will simply update between queue switches to show the respective queue output valid status.

The multi-queue device places its \overline{OV} flag output into High-Impedance based on the 3 bit ID code found in the 3 most significant bits of the read queue address bus, RDADD. If the 3 most significant bits of RDADD match the 3 bit ID code setup on the static inputs, ID0, ID1 and ID2 then the \overline{OV} flag output of the respective device will be in a Low-Impedance state. If they do not match, then the \overline{OV} flag output of the respective device will be in a High-Impedance state. See Figure 13, *Output Valid Flag Timing* for details of flag operation, including when more than one device is connected in expansion.

ALMOST FULL FLAG

As previously mentioned the multi-queue flow-control device provides a single Programmable Almost Full flag output, \overline{PAF} . The \overline{PAF} flag output provides a status of the almost full condition for the active queue currently selected on the write port for write operations. Internally the multi-queue flow-control device monitors and maintains a status of the almost full condition of all queues within it, however only the queue that is selected for write operations has its full status

output to the $\overline{\text{PAF}}$ flag. This dedicated flag is often referred to as the “active queue almost full flag”. The position of the $\overline{\text{PAF}}$ flag boundary within a queue can be at any point within that queue's depth. This location can be user programmed via the serial port or one of the default values (8 or 128) can be selected if the user has performed default programming.

As mentioned, every queue within a multi-queue device has its own almost full status, when a queue is selected on the write port, this status is output via the $\overline{\text{PAF}}$ flag. The $\overline{\text{PAF}}$ flag value for each queue is programmed during multi-queue device programming (along with the number of queues, queue depths and almost empty values). The $\overline{\text{PAF}}$ offset value, m , for a respective queue can be programmed to be anywhere between '0' and 'D', where 'D' is the total memory depth for that queue. The $\overline{\text{PAF}}$ value of different queues within the same device can be different values.

When queue switches are being made on the write port, the $\overline{\text{PAF}}$ flag output will switch to the new queue and provide the user with the new queue status, on the second cycle after a new queue selection is made, on the same WCLK cycle that data can actually be written to the new queue. That is, a new queue can be selected on the write port via the WRADD bus, WADEN enable and a rising edge of WCLK. On the second rising edge of WCLK following a queue selection, the $\overline{\text{PAF}}$ flag output will show the full status of the newly selected queue. The $\overline{\text{PAF}}$ flag output is double register buffered, so when a write operation occurs at the almost full boundary causing the selected queue status to go almost full the $\overline{\text{PAF}}$ will go LOW 2 WCLK cycles after the write. The same is true when a read occurs, there will be a 2 WCLK cycle delay after the read operation.

So the $\overline{\text{PAF}}$ flag delays are:

from a write operation to $\overline{\text{PAF}}$ flag LOW is $2 \text{ WCLK} + t_{\text{WAF}}$

The delay from a read operation to $\overline{\text{PAF}}$ flag HIGH is $t_{\text{SKEW2}} + \text{WCLK} + t_{\text{WAF}}$
Note, if t_{SKEW} is violated there will be one added WCLK cycle delay.

The $\overline{\text{PAF}}$ flag is synchronous to the WCLK and all transitions of the $\overline{\text{PAF}}$ flag occur based on a rising edge of WCLK. Internally the multi-queue device monitors and keeps a record of the almost full status for all queues. It is possible that the status of a $\overline{\text{PAF}}$ flag may be changing internally even though that flag is not the active queue flag (selected on the write port). A queue selected on the read port may experience a change of its internal almost full flag status based on read operations. The multi-queue flow-control device also provides a duplicate of the $\overline{\text{PAF}}$ flag on the $\overline{\text{PAF}}[3:0]$ flag bus, this will be discussed in detail in a later section of the data sheet.

See Figures 22 and 23 for Almost Full flag timing and queue switching.

ALMOST EMPTY FLAG

As previously mentioned the multi-queue flow-control device provides a single Programmable Almost Empty flag output, $\overline{\text{PAE}}$. The $\overline{\text{PAE}}$ flag output provides a status of the almost empty condition for the active queue currently

selected on the read port for read operations. Internally the multi-queue flow-control monitors and maintains a status of the almost empty condition of all queues within it, however only the queue that is selected for read operations has its empty status output to the $\overline{\text{PAE}}$ flag. This dedicated flag is often referred to as the “active queue almost empty flag”. The position of the $\overline{\text{PAE}}$ flag boundary within a queue can be at any point within that queue's depth. This location can be user programmed via the serial port or one of the default values (8 or 128) can be selected if the user has performed default programming.

As mentioned, every queue within a multi-queue device has its own almost empty status, when a queue is selected on the read port, this status is output via the $\overline{\text{PAE}}$ flag. The $\overline{\text{PAE}}$ flag value for each queue is programmed during multi-queue device programming (along with the number of queues, queue depths and almost full values). The $\overline{\text{PAE}}$ offset value, n , for a respective queue can be programmed to be anywhere between '0' and 'D', where 'D' is the total memory depth for that queue. The $\overline{\text{PAE}}$ value of different queues within the same device can be different values.

When queue switches are being made on the read port, the $\overline{\text{PAE}}$ flag output will switch to the new queue and provide the user with the new queue status, on the second cycle after a new queue selection is made, on the same RCLK cycle that data actually falls through to the output register from the new queue. That is, a new queue can be selected on the read port via the RDADD bus, RADEN enable and a rising edge of RCLK. On the second rising edge of RCLK following a queue selection, the data word from the new queue will be available at the output register and the $\overline{\text{PAE}}$ flag output will show the empty status of the newly selected queue. The $\overline{\text{PAE}}$ flag output is double register buffered, so when a read operation occurs at the almost empty boundary causing the selected queue status to go almost empty the $\overline{\text{PAE}}$ will go LOW 2 RCLK cycles after the read. The same is true when a write occurs, there will be a 2 RCLK cycle delay after the write operation.

So the $\overline{\text{PAE}}$ flag delays are:

from a read operation to $\overline{\text{PAE}}$ flag LOW is $2 \text{ RCLK} + t_{\text{RAE}}$

The delay from a write operation to $\overline{\text{PAE}}$ flag HIGH is $t_{\text{SKEW2}} + \text{RCLK} + t_{\text{RAE}}$
Note, if t_{SKEW} is violated there will be one added RCLK cycle delay.

The $\overline{\text{PAE}}$ flag is synchronous to the RCLK and all transitions of the $\overline{\text{PAE}}$ flag occur based on a rising edge of RCLK. Internally the multi-queue device monitors and keeps a record of the almost empty status for all queues. It is possible that the status of a $\overline{\text{PAE}}$ flag may be changing internally even though that flag is not the active queue flag (selected on the read port). A queue selected on the write port may experience a change of its internal almost empty flag status based on write operations. The multi-queue flow-control device also provides a duplicate of the $\overline{\text{PAE}}$ flag on the $\overline{\text{PAE}}[3:0]$ flag bus, this will be discussed in detail in a later section of the data sheet.

See Figures 24 and 25 for Almost Empty flag timing and queue switching.

TABLE 4 — FLAG OPERATION BOUNDARIES & TIMING

Output Valid, \overline{OV} Flag Boundary	
I/O Set-Up	\overline{OV} Boundary Condition
In36 to out36 (Almost Empty Mode) (Both ports selected for same queue when the 1 st Word is written in)	\overline{OV} Goes LOW after 1 st Write (see note 1 below for timing)
In36 to out36 (Packet Mode) (Both ports selected for same queue when the 1 st Word is written in)	\overline{OV} Goes LOW after 1 st Write (see note 2 below for timing)
In36 to out18 (Both ports selected for same queue when the 1 st Word is written in)	\overline{OV} Goes LOW after 1 st Write (see note 1 below for timing)
In36 to out9 (Both ports selected for same queue when the 1 st Word is written in)	\overline{OV} Goes LOW after 1 st Write (see note 1 below for timing)
In18 to out36 (Both ports selected for same queue when the 1 st Word is written in)	\overline{OV} Goes LOW after 1 st Write (see note 1 below for timing)
In9 to out36 (Both ports selected for same queue when the 1 st Word is written in)	\overline{OV} Goes LOW after 1 st Write (see note 1 below for timing)

NOTE:

1. \overline{OV} Timing

Assertion:

Write to \overline{OV} LOW: $t_{SKEW1} + RCLK + t_{ROV}$

If t_{SKEW1} is violated there may be 1 added clock: $t_{SKEW1} + 2 RCLK + t_{ROV}$

De-assertion:

Read Operation to \overline{OV} HIGH: t_{ROV}

2. \overline{OV} Timing when in Packet Mode (36 in to 36 out only)

Assertion:

Write to \overline{OV} LOW: $t_{SKEW4} + RCLK + t_{ROV}$

If t_{SKEW4} is violated there may be 1 added clock: $t_{SKEW4} + 2 RCLK + t_{ROV}$

De-assertion:

Read Operation to \overline{OV} HIGH: t_{ROV}

Full Flag, \overline{FF} Boundary	
I/O Set-Up	\overline{FF} Boundary Condition
In36 to out36 (Both ports selected for same queue when the 1 st Word is written in)	\overline{FF} Goes LOW after D+1 Writes (see note below for timing)
In36 to out36 (Write port only selected for queue when the 1 st Word is written in)	\overline{FF} Goes LOW after D Writes (see note below for timing)
In36 to out18 (Both ports selected for same queue when the 1 st Word is written in)	\overline{FF} Goes LOW after D Writes (see note below for timing)
In36 to out18 (Write port only selected for queue when the 1 st Word is written in)	\overline{FF} Goes LOW after D Writes (see note below for timing)
In36 to out9 (Both ports selected for same queue when the 1 st Word is written in)	\overline{FF} Goes LOW after D Writes (see note below for timing)
In36 to out9 (Write port only selected for queue when the 1 st Word is written in)	\overline{FF} Goes LOW after D Writes (see note below for timing)
In18 to out36 (Both ports selected for same queue when the 1 st Word is written in)	\overline{FF} Goes LOW after $([D+1] \times 2)$ Writes (see note below for timing)
In18 to out36 (Write port only selected for queue when the 1 st Word is written in)	\overline{FF} Goes LOW after $(D \times 2)$ Writes (see note below for timing)
In9 to out36 (Both ports selected for same queue when the 1 st Word is written in)	\overline{FF} Goes LOW after $([D+1] \times 4)$ Writes (see note below for timing)
In9 to out36 (Write port only selected for queue when the 1 st Word is written in)	\overline{FF} Goes LOW after $(D \times 4)$ Writes (see note below for timing)

NOTE:

D = Queue Depth

\overline{FF} Timing

Assertion:

Write Operation to \overline{FF} LOW: t_{WFF}

De-assertion:

Read to \overline{FF} HIGH: $t_{SKEW1} + t_{WFF}$

If t_{SKEW1} is violated there may be 1 added clock: $t_{SKEW1} + WCLK + t_{WFF}$

Programmable Almost Full Flag, \overline{PAF} & \overline{PAFn} Bus Boundary	
I/O Set-Up	\overline{PAF} & \overline{PAFn} Boundary
in36 to out36 (Both ports selected for same queue when the 1 st Word is written in until the boundary is reached)	$\overline{PAF}/\overline{PAFn}$ Goes LOW after D+1-m Writes (see note below for timing)
in36 to out36 (Write port only selected for same queue when the 1 st Word is written in until the boundary is reached)	$\overline{PAF}/\overline{PAFn}$ Goes LOW after D-m Writes (see note below for timing)
in36 to out18	$\overline{PAF}/\overline{PAFn}$ Goes LOW after D-m Writes (see below for timing)
in36 to out9	$\overline{PAF}/\overline{PAFn}$ Goes LOW after D-m Writes (see below for timing)
in18 to out36	$\overline{PAF}/\overline{PAFn}$ Goes LOW after $([D+1-m] \times 2)$ Writes (see note below for timing)
in9 to out36	$\overline{PAF}/\overline{PAFn}$ Goes LOW after $([D+1-m] \times 4)$ Writes (see note below for timing)

NOTE:

D = Queue Depth

m = Almost Full Offset value.

Default values: if DF is LOW at Master Reset then m = 8
if DF is HIGH at Master Reset then m = 128

\overline{PAF} Timing

Assertion: Write Operation to \overline{PAF} LOW: $2 WCLK + t_{WAF}$

De-assertion: Read to \overline{PAF} HIGH: $t_{SKEW2} + WCLK + t_{WAF}$

If t_{SKEW2} is violated there may be 1 added clock: $t_{SKEW2} + 2 WCLK + t_{WAF}$

\overline{PAFn} Timing

Assertion: Write Operation to \overline{PAFn} LOW: $2 WCLK^* + t_{PAF}$

De-assertion: Read to \overline{PAFn} HIGH: $t_{SKEW3} + WCLK^* + t_{PAF}$

If t_{SKEW3} is violated there may be 1 added clock: $t_{SKEW3} + 2 WCLK^* + t_{PAF}$

* If a queue switch is occurring on the write port at the point of flag assertion or de-assertion there may be one additional WCLK clock cycle delay.
